Remarks.—The important and instructive features of this case are, first, *the history of a long-standing catarrhal affection* (of at least seven years' duration) *preceding any symptom referable to the lungs.* Although not holding myself in abeyance to the history of patients as given by themselves, still the exceptional intelligence displayed by this individual in relating his symptoms, and their agreement with the local findings, induces me to believe that *the nasal catarrh preceded the pulmonary disease.* In other words, in the combined constitutional depression and pulmonary irritation, resulting from the mental and physical wear and tear, respiratory disturbances, dyspepsia, etc., following in the train of a long-neglected nasal catarrh, we recognize the precursors of a fatal pulmonary tuberculosis. The peculiar blanching of the intra-nasal mucous membrane, and also of the pharynx and larynx, afforded additional evidence of the existence of a pulmonary phthisis secondary to a hypertrophic rhinitis. Such an appearance is just the opposite to what we might expect to find in this affection, and therefore indicates the anæmia of phthisis, for, although the catarrhal hyperæmia had entirely disappeared, its pre-existence is presumable from the presence of the more persistent products, namely, the intra-nasal hypertrophies.

The circumscribed congested area upon the right vocal cord probably resulted from the rasping character of the efforts constantly employed to clear the larynx of irritating mucus. Its very existence constituted an additional source of irritation, and, although not to be designated as an ulcer, it is highly probable that this abraded surface would have eventually proved to be the starting-point of a phthisical process, in accordance with a pathological process already described by me.*

Case III.—Mr. ——, aged fifty-three, from Ohio, came to me, through the recommendation of his son, a patient referred to me by Dr. M. J. Roberts, of New York, in quest of relief from an annoying nasal catarrh. The malady had existed for many years. Much discomfort was caused by

* "Archives of Laryngology," vol. iv, p. 187.

the constant efforts required to remove a constant accumulation of thick, tenacious nasal mucus. Examination of the nostril revealed, among other signs of a rhinitis hypertrophica, the presence of an irregularly shaped posterior turbinated hypertrophy, occupying the right post-nasal fossa. The hypertrophy exhibited no signs of active congestion, but was dark-blue in color, evidently indicating much passive engorgement of the turbinated venous sinuses. The nasal mucous membrane, throughout almost its entire extent, presented the pallid hue of phthisical anæmia. Exploration of the chest demonstrated the existence of catarrhal phthisis, most markedly developed at the apex of the right lung.

Believing the posterior hypertrophy to be responsible for much of the patient's discomfort, I concluded it best to remove this source of irritation. I employed my nasal écraseur, easily encircling the hypertrophied tissue with a loop of No. 5 piano-wire. As might naturally be anticipated from the blanched appearance of the pituitary membrane, the operation was a bloodless one. The patient pronounced himself much benefited by the operation and after-treatment, and returned to his home well satisfied. This was in January, 1881. In July, 1882, I was informed that he had caught cold and was carried off by an attack of pneumonia, thus confirming my suspicions that his pulmonary phthisis would eventually lead to his death.

The son of the deceased, a man about thirty years of age, had, as I have already indicated, consulted me for relief from a chronic coryza. The coryza, I discovered, was due to an hereditary malformation of the septum and nasal chamber. I succeeded in rendering him comparatively free from his complaint by removing the offending deviation of the septum. He has enjoyed excellent health ever since. It was interesting and instructive to note the close resemblance between the forehead and face of the father and son. The frontal prominences of both projected so far forward as to place the forehead almost on a vertical plane with the face. The face beneath the overhanging forehead appeared unnaturally narrow, affording an example of Blumenbach's observation of the marked retrocession and contraction of the bones of the face in individuals exhibiting great cranial development.

The father was an intelligent man, and his son, utilizing excellent educational opportunities, developed unusual literary ability as the editor of a journal. The youngest, and only other son of the family, about whom I was consulted but never saw, I am informed possessed a rare degree of intelligence, and have a right to suspect that he possessed the cranial conformation of his father and brother.

A few days ago I was informed that this son had just fallen a victim to consumption. Despite the discouraging family history of the surviving son, I feel confident that *timely* treatment and care have sufficiently removed the impress of his unfortunate inheritance to enable him to live out his natural life.

Here, then, we have the mournful picture of a father, afflicted with a life-long catarrhal malady, eventually perishing with pulmonary tuberculosis, his eldest son harassed by a nasal catarrh traceable to a deviated septum, and another son, a young man, dying two years after the father with the same disease.

I might add other illustrations to the foregoing cases did not the typical character of those just reported make this unnecessary.

Treatment.—The treatment of these and similar cases is essentially one aimed at the direct cause of the disease—namely, the deviated septum and co-existing turbinated hypertrophies. It largely consists in the restoration of nasal symmetry by methods which facilitate the excision of bone and cartilage, and the removal of intra-nasal redundancies. A variety of instruments are therefore required, their character being determined by the density and situation of the offending structures. My regular office operating-set consists of my wire-snare nasal écraseur, and transfixion-needles for removing soft redundancies; a fenestrated cartilage forceps, tubular-spring forceps, beaked scissors, and trimming scissors for excising cartilage; and my rongeur forceps for cutting through bone. Nearly all the operations indicated by these instruments are, through the benumbing influence of cocaine and rhigolene anæsthesia, rendered bloodless and painless. Most of you are acquainted with my methods of operating, and, inasmuch as more than a mere reference to them would exceed the limits and not accord with the purpose of this paper, I must refer those ignorant of these procedures to my earlier publications.

Appropriate treatment should also be instituted to heal and contract the raw surfaces, to remove and prevent the reformation of nasal crusts in the atrophic forms of the disease, and to check excessive discharges of nasal mucus. In other words, to borrow an expression from Niemeyer, "Where there is the slightest suspicion of a predisposition to consumption, every catarrh, no matter how slight, is to be treated with the utmost care, which is not to be relaxed until the catarrh is entirely well."

Conclusions.—Briefly reviewing the subject-matter I have just presented, you will observe that, in determining the relations of nasal catarrh to pulmonary phthisis, I have, in the order of its origin and sequence, commenced by observing and interpreting the catarrhal manifestations as they occur in the nares, and have traced the gradual extension of the nasal disease to the larynx.

Within the larynx we discovered the catarrhal impress in the form of a chronic irritative hyperæmia of the larynx, brought about by the combined action of nasal discharges, habitual mouth-breathing, and inflammatory changes, chronic catarrhal hyperæmia of the larynx; to go a step further, ofttimes merges into an acute laryngitis, and this in turn may develop bronchitis. We recognize the deviated septum as a most common cause of nasal catarrh, producing this disease by pressure irritation, interference with nasal drainage, and unequal distribution of the nasal respiratory function. We have seen the importance of heredity as a factor responsible for the existence of certain forms of deviated septa, and noted the conditions indicating the hereditary character of these abnormalities.

Viewing the larynx as really the upper portion of the lung, although divorced from it on artificial anatomical grounds, we are often enabled to determine approximately,

by the appearance of the laryngeal and tracheal mucous membrane, what conditions may exist beyond the line of laryngoscopic vision, and thus complete our pathological picture, beginning in the nares and ending in the lungs.

It is hardly necessary for me to insist upon the value of the lessons to be derived from the early recognition of the clinical facts I have just presented. They at least offer something tangible as regards prophylaxis against phthisis or tuberculosis, for their successful treatment falls in the positive domain of surgery. The results are for the most part favorable and speak for themselves, provided the methods which I have proposed and published for removing redundancies or the remedying of defects are not commenced too late.

It is hardly necessary for me to add that great care should be exercised to properly discriminate between cases in which pulmonary phthisis or tuberculosis precedes or exists with nasal catarrh, and are, therefore, not related to the last mentioned affection as cause and effect, and those developed by a catarrhal affection. Being mindful of this, I have felt the necessity of sometimes giving details which were indispensable but which may have been wearisome. It must also be borne in mind that errors are likely to creep in from difficulty or carelessness in differentiating distortions of the septum resulting from injury from those dependent upon heredity. My experience, however, encourages me to state that, different from what you might probably imagine, in most instances, such a distinction, when properly made, constitutes a simple question of differential diagnosis. I have already referred to some of the rules which facilitate the recognition of the septum of heredity; and, were it advisable just here, I could mention other criteria of equal value. It is obvious that, in treating a subject of this kind, many questions present themselves, the proper interpretation of which must, for the present at least, baffle scientific investigation — such, for instance, as the proneness of some families with malformed septa to phthisis or tuberculosis, while others, on the contrary, are afflicted with annoying sthenic but, as far as the life of the individual is concerned, harmless pulmonary maladies. These, among similar speculations, though perhaps partly explainable by ingenious hypothetical methods, must, nevertheless, for want of sufficient demonstrative and experimental evidence, prove for the most part unintelligible. But even in the contemplation of such obscure problems the earnest investigator may derive encouragement from Prof. Huxley's remark, that "whatever may be men's speculative doctrines, it is quite certain that the order of nature is constant, and that the chain of natural causation is never broken."

25 East Thirty-first Street, N. Y.

The American Social Science Association held its annual meeting at Saratoga Springs on Wednesday, September 9th. Papers were read by Dr. Lucy M. Hall, of Brooklyn, on "The Physical Training of Women"; by Dr. D. A. Robinson, of Bangor, Me., on "The Therapeutics of Exercise"; by Dr. Grace Peckham, of New York, on "The Influence of City Life on Health and Development"; and by Dr. Charles Harrington, of Boston, on "The Adulteration of Food, particularly in Cities." Other papers were read by Miss Marian Talbot and Mr. C. F. Wingate.

PRACTICAL COMMENTS ON THE USE AND ABUSE OF COCAINE;

SUGGESTED BY ITS INVARIABLY SUCCESSFUL EMPLOYMENT IN MORE THAN A THOUSAND MINOR SURGICAL OPERATIONS.

By WILLIAM S. HALSTED, M. D.

Neither indifferent as to which of how many possibilities may best explain, nor yet at a loss to comprehend, why surgeons have, and that so many, quite without discredit, could have exhibited scarcely any interest in what, as a local anæsthetic, had been supposed, if not declared, by most so very sure to prove, especially to them, attractive, still I do not think that this circumstance, or some sense of obligation to rescue fragmentary reputation for surgeons rather than the belief that an opportunity existed for assisting others to an appreciable extent, induced me, several months ago, to write on the subject in hand the greater part of a somewhat comprehensive paper, which poor health disinclined me to complete.

In the mean time we have been reading of unsuccessful and occasionally fortunate hypodermic experiments with cocaine, without finding a hint as to possible causes for the very positive contradictions, or even an intimation that they were not precisely such as must have been expected.

And just now appears a frank confession from Dr. Garrigues,* who narrates his case with so much care and in such detail as to permit one to say positively why cocaine in this instance should have proved inefficacious and have seemed inert, and as to encourage me to do this, and then perhaps to recommend attention to a few of the facts about cocaine which in the records of my personal observations are styled useful, preferably such as may enable us to better recognize proper conditions and cases for its employment, having indicated methods which insure success.

Like most other contributions to cocaine's subcutaneous scrap-bag, the latest stakes its own and the drug's reputation on the luck of a single experiment; and again, like many of them, records the "failure of cocaine hydrochlorate to produce anæsthesia." Were success, however, and not failure, the rule, less conspicuous would the occasion have become for any one (of the majority) to publish the reasons why cocaine injections should have accomplished nothing for a few others (the minority), and as much feebler the excuse for circulating the results of inexperience, as the possibilities to continue unformed had been reduced. All things considered, the journal contributions and personal communications, the interrogations and opportunities for observing the methods of others, incline me to regard the ultimate conviction of Dr. Garrigues as a fair expression of average notions on the reliability and practical value of subcutaneous injections of cocaine.

I feel sure, furthermore, that the aforesaid observer will be gratified at finding his communication offered up in explanation of honest differences of opinion.

* "N. Y. Med. Jour.," August 29, 1885, p. 240, "Failure of Cocaine Hydrochlorate to produce Anæsthesia," by Henry J. Garrigues, M. D.

Proposing to enlarge an artificially small vaginal orifice by incision, he says (*loc. cit.*):

"Since here was only a thin layer of skin and mucous membrane to be cut, both surfaces of which were easily accessible, it seemed to be a case peculiarly well fitted for local anæsthetization. I began by painting both surfaces with a four-per-cent. solution of hydrochlorate of cocaine. When two grains of the salt had been used in this way and there was not the slightest diminution in the sensitiveness of the skin, I injected a quarter of a grain hypodermically into the tissue to be divided, and continued soaking the skin and the mucous membrane."

While in sympathy with Dr. G.'s desire to test, where convenient, the statement of others by an observation of his own, it is not so evident why he should expect cocaine, in this particular instance, to make an exception in his favor. For, when it has been repeatedly observed that a four-per-cent. aqueous solution does not anæsthetize the sound skin, fresh demonstrations of the fact should not cause surprise.

"About seven minutes after the first hypodermic injection I repeated it, introducing the needle from the posterior commissure all the way back as far as the tissues were to be divided. In spite of the previous injection, this caused as much pain as if nothing had been done before to produce anæsthesia."

Injected *under* the skin, cocaine probably produces anæsthesia of the same only when made into or very near a nerve-filament or nerve-trunk; and then, according to circumstances, the anæsthesia persists, more or less complete, from ten minutes to an hour or more. After an injection into the skin, the anæsthetic effects seldom last more than two or three minutes, and often vanish in less than a minute.

If Dr. G. injected strictly under the skin, he might, by chance, have paralyzed some nerve-filament; but there is scarcely a possibility that its distribution could have corresponded to the line of the incision, and a strong improbability that any filament was encountered, because no trace of anæsthesia remained.

On the other hand, it would be strange if none of the solution had been forced into the skin layer of this thin membrane; in fact, judging from the description of the part, I doubt if one could have avoided doing so. We may suppose, therefore, that certain areas of skin were anæsthetized for two or three minutes, and that the operator, by waiting seven minutes, lost his opportunity.

In the light of a little experience, such events would not be regarded as unusual.

"This second time, likewise, a quarter of a grain of the salt was injected slowly, while withdrawing the needle, over the whole tract with which it came in contact. Finally I bathed again the two surfaces until I had used in all five grains of hydrochlorate of cocaine, one half grain of which had been injected hypodermically. This application of a four-per-cent. solution had then been kept up for twenty-five minutes."

Here, again, the incision should have been made as soon as possible after the injection, and the latter *into*, not *under*, the skin.

"In spite of this thorough and protracted application of a comparatively strong solution of cocaine, the sensibility was not lessened the least, so far as the complaints and screams of the patient could be used as a measure of her pain."

There suggests itself the propriety of testing the sensibility before cutting.

(*To be concluded.*)

Book Notices.

Praktische Beiträge zur Kinderheilkunde. III. Heft. Die Verdauungskrankheiten der Kinder. Von Dr. Adolf Baginsky, Privatdocent der Kinderheilkunde an der Universität Berlin. Mit 3 Tafeln mikroscopischer Abbildungen. Tübingen: H. Laupp, 1884. Pp. 232. [Price, 6 M.]

This monograph, the third of the series, contains a thorough and quite exhaustive discussion of the commoner diseases of the digestive system, the rarer forms not being noticed.

It is divided into five chapters, in which are described, respectively, primary dyspeptic gastro-intestinal catarrh, acute gastro-enteritis (cholera infantum nostras), acute follicular entero-colitis, secondary subacute or chronic gastro-intestinal catarrh, and gastro-intestinal atrophy (atrophia infantum). The author's investigations into the subject of ætiology lead him to the conclusion that these diseases are not influenced by sex, atmospheric pressure, rainfall, fluctuations in ground water, or dentition. The great causes are the heat of summer, the mode of feeding (five sixths of the fatal cases being in those who were fed artificially), and age. Over ninety-five per cent. of the persons who died of diseases of the digestive organs in Berlin were under five years of age.

Special attention has been paid to the pathological side of the subject. Both the gross and the microscopical lesions are exceedingly well described, and twenty-nine original drawings are given in an appendix illustrating the microscopical appearances of organs, discharges, and microbes. Into the investigation of the question of bacilli he has entered quite fully. The dejections furnished an immense number and variety of microorganisms. The most characteristic in the simple gastro-intestinal catarrh were little rods and cocci, their number varying with the development of the case. In true cholera infantum the bacilli most abundant were broken rods, not stained easily by either Bismarck-brown or gentian-violet, but best seen by adding liquor potassæ to the fresh specimen. These were found very constantly both in the walls of the intestine, particularly in the lymph vessels and follicles, and in the dejections. Although the author has as yet made no experiments with cultivations from this bacillus, he is strongly inclined to regard it as the cause of the disease.

In the treatment of simple catarrh, after the bowels have been cleared by either castor-oil or an enema, antiseptics are relied upon very largely to control the disease. Of these he prefers resorcin to all others, giving it in doses up to one grain every two or three hours to a child a year old. Large doses of this drug are not to be used. Iodoform in one- or two-grain doses he has found of value, and also bismuth. Opium may be advantageously combined with any one of these three drugs. It is specially indicated where increased peristalsis is a prominent symptom. It favors rather than prevents decomposition. Simple and astringent enemata are highly spoken of in almost all forms of diarrhœal disease, but especially in cases of colitis.

One or two grains of nitrate of silver are added to each enema in cases of frequent mucous and bloody stools, tincture of opium when the tenesmus is great—injected with water, never with starch. Injections should be made through a soft catheter or a rectal tube carried high into the bowel.

In choleraic diarrhœa astringents are useless. The prognosis is bad under almost any treatment, but the best results are reported from free stimulation, hypodermically if the vomiting is persistent, and irrigations of the bowel.

The author takes issue with Biedert regarding the existence of "fat diarrhœa" as a peculiar form of disease. Fat is found in the stools of every child suffering from indigestion while nursing; it may be present in very large amount without any diarrhœa. Examination of the pancreas has so far, in his own cases, been without result.

The diagnosis of gastric indigestion is to be made, he states, not so much from the condition of the vomited matters in curds, or their sour reaction, as from the fact that food undigested is vomited at a considerable time after it is taken. The stomach of a nursing infant should be empty in an hour, or at least in an hour and a half, after taking food.

The last chapter, upon atrophy, is exceedingly good. The stools in this form are pasty and homogeneous, alternating with those which consist almost entirely of watery elements. They all have an exceedingly foul odor, and particles of food are not visible; they contain no epithelium and no cell-elements. The food is not digested, but its appearance is completely destroyed by decomposition. The lesions well explain the symptoms, especially the extreme emaciation which exists. There is an extensive proliferation of new connective tissue in the submucosa, and the contraction of this and pressure upon the glandular structures leads to the destruction and disappearance of the latter, so that neither absorption nor secretion can take place in the bowel. The condition is a hopeless one when it is reached.

This book is worthy of a more extended review than our space here will permit. Throughout the author shows a practical grasp of his subject. We should like to see the book given to American readers in a translation.

Correspondence.

LETTER FROM BOSTON.

The Boston Water-Supply.

BOSTON, *September 8, 1885.*

IF the newspapers are to be believed, Boston is to-day without a drop of good water to drink. We had just got over our cholera scare, and were thinking of bringing our families and patients home, when the Mayor sent a document to the Water Board which caused considerable consternation. For years we had been receiving our water from Lake Cochituate, and the supply equaled the demand, and was good, but, when the surrounding territory was annexed, that supply ceased to be large enough, even with that from Mystic River (which came to us through the taking in of Charlestown) and the water from Jamaica Pond, Jamaica Plain, and Roxbury; so that, in June, 1874, the Hon. Samuel C. Cobb, at that time Mayor of Boston, appointed a committee of three physicians to examine and report upon various sources for a new supply. The committee consisted of Dr. Charles W. Swan, Prof. Edward S. Wood, and Dr. Henry P. Bowditch, and they carefully examined the waters of the Sudbury, Mystic, Shanshine, and Charles Rivers. They said: "The resultant estimate, therefore, of the sanitary qualities of the four rivers places them in the following order of preference: 1. Shanshine. 2. Charles. 3. Sudbury. 4. Mystic." On account of superior storage facilities, the Sudbury was chosen.

It is unnecessary to go into details as to the mechanical part of the work; but, in order that your readers may have some idea of how we are supplied now, I will say that the Sudbury River was diverted from its natural channel, and, by means of storage reservoirs, Beaver-Dam Brook and Farm Pond brought in with the Cochituate system. At the time that the Farm Pond plan was being considered by the city government, those most interested in the work wished to have the bottom of the pond (which was a peaty soil) and the conduits dredged and a hard bottom of sand and gravel substituted for the loam, maintaining that such a procedure would greatly benefit the water, and that the loam could be used by the city in other work it was contemplating. On account of the additional cost, this was not done. The new system had not been long in operation before a change in the color and taste of the water was noticed. The taste kept growing worse and worse until the so-called "cucumber taste" was reached. Many theories were advanced as to what caused this, but nothing satisfactory was offered until a gentleman from Baltimore examined the water and reported that this peculiar condition was due to a growth which took its origin from the peaty soil, the flow of the water being so slow that the growth was not interfered with. The city authorities now ordered—what they should have ordered at first—the removal of the loam and its replacement with sand and gravel. This done, the cucumber taste disappeared. During this period the hydrant-water was used only for bathing and cooking; for drinking purposes people bought spring water from various sources, and it was astonishing to see the amount that a few springs would furnish—so that many believed that charcoal or some other filter was all that was necessary to create a "spring."

It is not necessary to go into the politics of the subject and state how two water boards were suspended on account of want of confidence, as all this has been amply made public in the newspapers. In May, 1884, Dr. Henry J. Barnes, in a paper upon "Sewerage Systems and the Epuration of Sewage by Irrigation and Agriculture," read before the Section of Clinical Medicine and Hygiene of the Suffolk District Medical Society, showed that our water-supply was contaminated with the sewage of the Woman's Prison at Sherburn, in addition to other sources well known, from which he had for years been trying to get relief by legislation. As an outcome of this paper, committees were appointed by the Norfolk and Suffolk Medical Societies to investigate the sources of our water-supply, and report. They have done so, and their conclusions are not of a nature to give confidence in the purity of the water. They state that all the fountain-heads are polluted with the sewage of villages and towns, which drain either into the soil or directly into the brooks from which the supply is derived; that numerous factories, tanneries, and other industrial establishments are drained directly into the rivers; and that, even where screens and filters are used to keep out offensive matter, they do not act sufficiently to be of service. Of course, these statements have in several instances been denied, and in others the local authorities assert that the condition of things has been greatly exaggerated. The fact that our water-sheds are among thickly settled communities can not be denied. These communities have to dispose of their sewage, and, no matter how that is done, some of it must flow into and follow the watercourses.

This question of water-supply and the disposal of sewage is one that has been constantly before the community, and various suggestions have been offered; but heretofore the trouble has been that nobody in the city government was really responsible. Now, by our new city charter, the Mayor is responsible for everything, and Mayor O'Brien has given his word that he and the Water Board will investigate the subject carefully and thoroughly, and, if possible, remedy the trouble, even if it becomes necessary to take water from Lake Winnepesaukee, and build a sewer from the mountains to the ocean.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.
NEW YORK, SATURDAY, SEPTEMBER 12, 1885.

A PROPOSED NEW NATIONAL MEDICAL ASSOCIATION.

The deep dissatisfaction of the profession with the American Medical Association has found renewed and energetic expression week by week since we first insisted upon its responsibility for the deplorable prospect now before the Ninth International Medical Congress, in case the attempt should yet be made to hold the session of 1887 in this country. This feeling of dissatisfaction is deeply tinged with indignation and disgust. It is entertained by honorable physicians in every quarter of the United States, as is amply shown by the extracts we have published of late from a great number of our contemporaries. It was hoped at first that the unutterably foolish and presumptuous action taken at New Orleans was in a certain sense an accident; that it would be rescinded when its real purport and the disfavor with which it met came to be understood by the leaders of the association, so that even the success of the Congress would not be seriously imperiled; and that the incident would, in the long run, prove a blessing in disguise by demonstrating the necessity of taking prompt measures to remodel the organization. Although we have been quite as decided as any of our contemporaries in denouncing the association, we nevertheless shared the hopeful feeling alluded to until it became evident that the managers of the organization were determined to give no heed to the voice of the profession. But it is quite manifest now, not only that the profession at large is to be disregarded, but that even the members of the association can not be counted on to continually hold in check the schemers that control it. Nothing but a radical re-organization would put it on a satisfactory basis, and the outlook for such a regeneration is not promising. It must be conceded, therefore, that the rapidly increasing number of those who hold that the American Medical Association "must go" are taking a position that is not at all unreasonable.

But a national organization of some sort we must have, although the less it occupies itself with politics the better. Several suggestions have been made as to the establishment of a new society, but none of them have struck us as quite so feasible as one which is outlined in a communication lately sent to us by a member of the profession who modestly asks us to withhold his name. We will say, however, that he is a gentleman of deservedly high position, and one for whose judgment those who know him have the very highest respect. Like many others, who have been falsely accused of being actuated by a feeling of hostility toward the American Medical Association, his present despair of the regeneration of that body has been slowly brought about, and his proposition would never have been broached, or even taken shape in his mind, but for the indisputable and confirmed degeneracy of the association.

Our correspondent thus sets forth his plan: "I think we need a medical association corresponding to the French Academy of Medicine; that it should be few in numbers, filling its own vacancies, and so honorable a body that membership in it would carry the highest reward that medical men here would have to hope for. Its annual (business) meeting should be held always at the same place (? Washington) and at the same time of year; its semi-annual, or scientific, meeting movable by vote of its members from city to city. The original organization might well take its inception in a small gathering of eminent physicians, who should send out a circular, signed by a committee composed of representative men from the principal cities, inviting the appointment of delegates to a nominating convention, which should appoint the first half of the Academy. Let the first half proceed at its ample leisure to fill its own numbers."

Our correspondent adds that his idea has met with hearty support from the influential men to whom he has been able to suggest it. It certainly seems to us feasible and judicious. Matters of detail would of course come up for settlement in considerable variety, but the essentials of the plan are such as could scarcely fail to secure the establishment of a body of men quite above the petty idea of geographical representation, creditable to the country from a scientific point of view, and conservative in the few matters of legislation that they would tolerate. No fraction, even, of such a body—supposing a meeting to be scantily attended—could be "captured" by schemers or cajoled by buncombe. The author of this plan says that he is quite aware that it could not be carried out at once—not soon enough, indeed, to meet the exigency now upon us in connection with the International Congress — but it is for the future that we must provide. It is not without due consideration that we have resolved to favor the idea, but we do so now without reserve, and we trust that the profession will take it into serious consideration. That there is a widespread inclination to take some such action we have no doubt.

"THE WAY ACROSS IS LONG; THE FEAR OF THE SEA IS STRONG."

With this quaint statement of a truism does Prof. Hansen-Grut, of Copenhagen, whose letter to a New York physician we publish elsewhere in this issue, tenderly disguise the disgust that our European colleagues are beginning to feel at the wretched results of the American Medical Association's meddlesome and revolutionary course in the matter of the Ninth International Medical Congress. But politeness will not long cover that disgust. How keen a feeling of indignation is entertained in our own country we can not better express than by quoting from an editorial article in the September number of the "Pacific Medical and Surgical Journal," of San Francisco (on the cover of which journal, by the way, appears the name of R. Beverly Cole, M. D., M. R. C. S., as a collaborator). Our esteemed contemporary prints Sir James Paget's letter toDr. I. Minis Hays, and adds the following comment:

"It will be seen from this that the power of making the necessary arrangements has never been put in the hands of the British, Danish, or any other national medical society; but intrusted to a few men of established reputation, who co-operated with the Executive Committee of the Congress. Perhaps the American Medical Association will now be convinced that they have meddled in a business over which they had no direct authority; that, in making themselves the instruments of men who have since boasted of the mischief they have done, they have struck a blow at medical culture, the effects of which only the lapse of long years can remove. The 'American Medical Journal' has vainly reasoned with and finally abused as obstructionists to the work of organization those men who have refused to acknowledge the supremacy of the association. Let us hope that its editor will now see that they were right in so doing; that the only men recognized as a committee by the Medical Congress were the American delegates to Copenhagen; that these gentlemen are accountable to the Congress; that it is now their duty to utterly ignore the American Association as an organization, and continue to make the necessary arrangements for the convening of the Congress, which, according to the law of usage, it is their right to do. Should Dr. Billings and his colleagues not recognize the fact that they are the men intrusted by the Congress with making the arrangements, that they are answerable to that body, and that the American Medical Association has absolutely no authority over them in this matter, then the Executive Committee of the last Congress, which still exists, and will not be discharged until the next meeting, should take this matter into its own hands and arrange to hold the meeting in some other country."

We are sorry to say that the American Medical Association seems not to have the slightest glimmering of an idea that it has done anything wrong, although it finds itself at bay, and is ready to resort to tactics, such, for instance, as what it is pleased to regard as the compromise involved in throwing the membership in the Congress (a matter over which it has no control) open to the whole regular profession, while denying official positions to all but those it considers its friends. The eyes of our foreign colleagues are upon us. What will they think of the secrecy in which last week's committee meeting was shrouded? Are they not perfectly well aware that, if the meeting had really done anything calculated to set things right, the committee would not have concealed the fact, but would have made haste to publish it? Truly, our friends in Europe would find the way across long and the fear of the sea strong, but it looks as if they would not have to encounter either.

NEWS ITEMS, ETC.

The International Medical Congress.—In addition to the declinations already announced, those of Dr. R. P. Lincoln, of New York, and Dr. J. H. Kidder, of Washington, have been sent in.

A special meeting of the American Medical Association's new committee on the Congress was held at the Murray Hill Hotel, in New York, on Thursday and Friday of last week. About thirty members of the committee seem to have been present from first to last, but probably nothing like that number at any one time. The utmost secrecy was observed, reporters being excluded, and there appears to be ground for the inference that continued secrecy was enjoined upon those who were present. Nevertheless, certain facts have become known —among others, that Dr. Lewis A. Sayre, of New York, tendered his resignation from the committee, that Dr. N. S. Davis, of Chicago, was made secretary-general of the Congress, and that the so-called compromise was adopted of allowing all members of the regular profession to register and pay their fees, but not to hold office in the Congress unless by virtue of membership in some society in affiliation with the American Medical Association.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 8, 1885:

DISEASES.	Week ending Sept. 1.		Week ending Sept. 8.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	0	1	0	0
Typhoid fever	34	3	36	10
Scarlet fever	13	2	15	1
Cerebro-spinal meningitis	2	1	1	1
Measles	9	1	3	1
Diphtheria	21	11	35	15
Small-pox	0	0	2	0

The Health of Michigan.—In addition to his usual monthly statement, the secretary of the State Board of Health has issued a supplementary bulletin for August, in which he clearly shows the connection between the board's sanitary work and the decided decrease that he is enabled to record in the prevalence of a number of destructive diseases. The diminished prevalence of fevers and intestinal diseases is very marked.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 30, 1885, to September 5, 1885:*

Magruder, D. L., Lieutenant-Colonel and Surgeon. Granted leave of absence for fifteen days. S. O. 201, A. G. O., September 3, 1885.

Middleton, Passmore, Major and Surgeon. Assigned to duty as attending surgeon at these headquarters, vice Major J. V. D. Middleton, surgeon, hereby relieved. S. O. 131, Department of the Missouri, August 28, 1885.

Girard, Alfred C., Captain and Assistant Surgeon. Assigned to duty as post surgeon at Boise Barracks, Idaho Territory. S. O. 142, Department of the Columbia, August 22, 1885.

Davis, William B., Captain and Assistant Surgeon. Having reported for orders from leave of absence, assigned to duty at Fort Porter, N. Y., as post surgeon. S. O. 183, Department of the East, August 28, 1885.

Kane, John J., Captain and Assistant Surgeon. Upon expiration of his present leave of absence to be relieved from duty at Willet's Point, New York Harbor, and to report to commanding general, Department of Texas, for assignment to duty. S. O. 201, A. G. O., September 3, 1885.

Banister, John M., Captain and Assistant Surgeon. Assigned to temporary duty at Camp of Competitors, at Creedmoor, N. Y., arriving not later than September 4, 1885. S. O. 58, Division of the Atlantic, August 31, 1885.

Richards, Charles, Captain and Assistant Surgeon. To be relieved from duty in Department of the East, and to report to the commanding officer at Willet's Point, New York Harbor, for duty at that station. S. O. 201, C. S., A. G. O.

Kendall, William P., First Lieutenant and Assistant Surgeon (recently appointed). To report in person to the commanding general, Department of California, for assignment to duty. S. O. 201, A. G. O., September 3, 1885.

Society Meetings for the Coming Week:

Monday, *September 14th:* New York Ophthalmological Society (private); New York Medico-Historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

Tuesday, *September 15th:* New York Academy of Medicine (Section in Theory and Practice of Medicine); Medical Society of the County of Kings; Ogdensburg, N. Y., Medical Association; Connecticut River Valley Medical Association (Bellows Falls, Vt.).

Wednesday, *September 16th:* Northwestern Medical and Surgical Society of New York (private); Medical Society of the County of Allegany, N. Y. (quarterly); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society (clinico-pathological).

Thursday, *September 17th:* New York Academy of Medicine; New Bedford, Mass., Society for Medical Improvement (private).

Friday, *September 18th:* Chicago Gynæcological Society.

Saturday, *September 19th:* Clinical Society of the New York Post-Graduate Medical School and Hospital.

Letters to the Editor.

SMALL-POX AND VACCINATION.

Franklin, Pa., *August 1, 1885.*

To the Editor of the New York Medical Journal:

An editorial in your valuable journal of date August 8th, on the important subject of vaccination after the beginning of small-pox, induces me to ask the privilege of recording therein the following experience of my own:

On Monday I was called to see J. H., a farmer, who had returned home Saturday night sick. He was covered with an eruption which I thought was probably small-pox. The family of four children were removed from the house, leaving the old mother, his wife, and a babe of three months to occupy the same room with him. The mother was said to have been vaccinated; the wife and babe had not been.

On Tuesday I returned with a portion of a fresh crust of vaccine virus. I vaccinated the three with a small spring vaccinating lance, making probably six strokes, and beginning above. Wednesday the same was repeated lower down. Thursday, also, the same again, still lower. Sunday following the husband died of confluent small-pox, the wife, the babe, and the grandmother having occupied the room all the time, and the mother and babe slept in the bed with the patient.

The vaccination of Tuesday failed on all, that of Wednesday took effect on the babe and grandmother, and that of Thursday on the wife. The old woman had a few pustules of varioloid; the babe, a smart fever and a dozen or two pustules, which aborted promptly without pitting. The wife had no fever nor any sign of pustule; her vaccination was severe and the areola large, and she entirely escaped, though she had occupied the same bed with her husband for five successive nights previous to her vaccination, and for at least three nights after the smell and eruption were distinct, and would, I believe, be considered ripe enough to propagate the disease.

I have since, in four cases, vaccinated daily small-pox patients before the eruption was perfected, marking the lance strokes. In two of these, which turned out mild cases, the vaccination appeared to have some effect, as I thought, in modifying the severity of the disease. In the other two the lance strokes produced no effect, nor did the pustules of small-pox show on the cuts. But the experience in the four cases was such as to favor a resort to prompt and efficient vaccination as a hope of modifying a terrible disease, especially if resorted to early.

Stephen Bredin, M. D.

Proceedings of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of June 24, 1885.

The President, Dr. John A. Wyeth, in the Chair.

A Circumscribed Congenital Tumor of the Leg.—Dr. A. Jacobi presented a baby, eight months old, whose mother was sixteen years of age. The baby had a tumor on the outer aspect of the lower portion of the left leg, extending about one third of the distance around the leg and upward a distance of about 5 ctm.; its surface was a little above the surface of the surrounding integument. The skin as a whole could not be raised from the mass, which was of soft feel, and not nodulated. The tumor had grown slightly since birth. The diagnosis lay between congenital lipoma and local elephantiasis. The skin appeared to be hypertrophied, and it was by no means certain that it was not elephantiasis, which condition he had seen congenital in this neighborhood before.

The President asked if it might not be a congenital sarcoma, and said that he once saw a small congenital sarcoma on the chin of a boy which had the appearance of a mole or reduplication of the integument. After a year and a half the tumor grew rapidly and the boy died at two years and a half of an enormous sarcomatous tumor.

Dr. Jacobi thought that by this time the growth, if it were a sarcoma, would begin to manifest peculiar characters pointing to that condition. He hoped to have an opportunity to make a positive diagnosis from a microscopic examination of some of the tissue.

Salpingo-oophorectomy.—Dr. W. Gill Wylie said that in January last he presented to the society fourteen specimens of tubes and ovaries removed by laparotomy for disease of those organs. This evening he had another series of eleven specimens. The histories were largely similar to those in the first series. One of the eleven patients died, making a mortality of three out of the entire twenty-five cases. In this fatal case, as in the others, death was due to septic poisoning, and was in a hospital patient. In all the eleven cases, except two, there were evidences of local inflammation, and in almost all there was a history of peritonitis. The majority of the women were bedridden; the remainder were laboring women, and unable to make a living because of their disease. All were under observation several weeks, months, or a year or more, before the operation was performed. In reply to Dr. Amidon's question as to how many of the patients were hysterical, he said probably one fourth or one third. He was disposed to think those who had cystic degeneration of the ovaries without disease of the tubes were the ones likely to be hysterical. He had never seen a case of hysteria in which there was not found, if laparotomy was performed, a cyst in the deep stroma of the ovary. He was beginning to lose faith in the so-called ovarian dysmenorrhœa; in the great majority of cases it was caused by

hyperæsthesia of the mucous membrane at or near the os internum.

The PRESIDENT had seen some cases comparatively recently which had impressed upon him the great importance of two principles which should be observed in order to obtain success in abdominal surgery; the first was, to avoid septic matter entering the abdominal cavity; the other, to secure free drainage. It had usually been taught that rupture of the bladder with escape of urine into the peritoneal cavity was sure death. He had seen one case of recovery after washing out the peritoneal cavity with bichloride solution. In another case, in which the peritoneal cavity became infected by the escape of matter from cysts, it was washed out two or three times by being completely filled with a weak solution of corrosive sublimate, which prevented septic reaction or peritonitis, although the patient died of exhaustion.

Perineal Section and Internal Urethrotomy for Stricture and Urinary Fistulæ.—Dr. C. H. KNIGHT presented the bladder and penis removed from the body of a man, forty years of age, who died from poisoning by cyanide of potassium. Twelve years ago he had gonorrhœa, and a second attack two years later. Stricture developed, for which he used a sound for many years. There also appeared urinary fistulæ in the perinæum, for which he received no treatment until they were divided by Dr. Knight in 1883, who at the same time performed internal urethrotomy. Urine ceased to pass by the fistulæ almost altogether after the operation. The sounds were passed for some time. Subsequently the patient fell, and as a result a perineal abscess developed, and this was followed by a renewal of the fistulæ. The operation of division and of further enlargement of the urethra with the urethrotome was repeated, and, after healing of the wounds, no urine escaped by the fistulæ for five weeks, when a slight dribbling occurred. Shortly afterward the man committed suicide. At the autopsy the deep urethra showed an abscess cavity, capable of containing about two drachms. In the immediate neighborhood were four fistulæ, the largest of which readily admitted a No. 28 sound. The bladder walls were much thickened, and the capacity of the organ was markedly diminished. The appearance of the urethra led him to think the fistulæ resulted from rough usage during the passage of sounds.

Dr. J. H. RIPLEY had once performed perineal section and urethrotomy in a man sixty years of age who had not passed urine by the urethra for six years. The fistulæ healed and the urine was passed by the normal channel.

Fibro-sarcoma of the Naso-pharynx recurring Eleven Months after Operation.—Dr. R. P. LINCOLN presented the specimen, which had been removed from a lad, seventeen years of age, on whom he had operated, removing a similar but smaller growth eleven months ago by the galvano-cautery wire. The first specimen was presented before the society in October last. The patient failed to keep his promise to have the cauterizations repeated, and hence the re-development of the growth, which was larger and more vascular, and was with considerable difficulty completely removed. The base was broad. The case emphasized the importance of repeated cauterizations of the surface of attachment. In this way he believed all these tumors which could thus be reached (and he had found none which he could not thus reach) could be radically cured.

Fracture of the Occipital Bone.—Dr. W. P. WATSON presented the occipital bone of a young man who had probably received an injury from a stone. The three following days he was able to work, but on the evening of the third day complained of headache, and sent for a physician, who found him unconscious. The remaining clinical history was incomplete, but two or three hours before death there was profuse hæmorrhage from the nostrils. There were found at the autopsy a soft spot on the scalp in front of the occipital protuberance and infiltration of the scalp with blood. On the right side the occipital bone was fractured, the fracture extending into the foramen magnum; on the left side was a fracture which extended a shorter distance. There was slight congestion of the surface of the brain.

Ulceration of the Vocal Bands during Measles.—Dr. VAN SANTVOORD presented a larynx in which the vocal bands had become markedly ulcerated during the course of measles. The child suffered from a pharyngitis and broncho-pneumonia developing in the course of the exanthematous disease. While he had not made it a custom to examine the vocal bands in children who had died during the course of measles, unless there were symptoms pointing specially to them, he had not supposed that ulceration of the bands was common. He was, therefore, surprised to learn, on studying the literature of the subject, that this complication was very common.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Ninth Annual Meeting, held at Greenwich, Conn., Wednesday, Thursday, and Friday, August 26, 27, and 28, 1885.

The President, Dr. W. A. HARDAWAY, of St. Louis, in the Chair.

(*Concluded from page 272.*)

Thursday's Proceedings.

Officers for the Ensuing Year were elected as follows: President, Dr. E. Wigglesworth, Boston; Vice-Presidents, Dr. I. E. Atkinson, Baltimore, and Dr. A. R. Robinson, New York; Secretary, Dr. G. H. Tilden, Boston; Treasurer, Dr. H. W. Stelwagon, Philadelphia. Dr. E. B. Bronson, of New York, was elected to membership. It was decided to hold the next meeting the last Wednesday of August, 1886, at Indian Harbor Hotel, Greenwich, Conn.

Dysidrosis.—Dr. G. H. FOX gave a brief description of two cases. The first one, for want of a better term, he classed under this heading. The patient was twenty-nine years of age, and had always perspired freely. Four years ago the eruption began on the palms of the hand, and had persisted. The soles of the feet had also been affected at one time. The skin of the hands was decidedly thick and had a dark hue, and was dotted with numerous elevations of epidermis, averaging in size that of a hemp-seed. The patient had never seen any moisture in connection with this. There had been no itching. The skin never peeled off. Puncture with a needle revealed no serum or fluid of any kind.

The second case was that of a woman aged forty-five, a cook, whose general health was good. The present trouble began five years ago. The eruption was on the face, and consisted of numerous large and small vesicles containing clear fluid.

Mycological Studies in Tinea Favosa and Tinea Trichophytina.—Dr. A. R. ROBINSON, of New York, prefaced a paper on this subject with a few general remarks. The epidermis of different individuals differed in susceptibility to these parasites. Children were more apt to suffer with tinea trichophytina and favus, while adults more frequently presented tinea versicolor. All children were not equally susceptible. In many cases of parasitic disease there was impaired vitality previous to the development of the affection. The author then gave an account of his investigations to determine the exact anatomical seat of the parasitic diseases in question, and to determine the changes which they produced in surrounding tissues. The con-

clusion was that in favus the rete was not affected until the later stages, when ulceration had made its appearance. The parasite confined itself more particularly to the corneous layer. The parasite of tinea trichophytina in some cases passed down into the rete, while in others it did not. A number of sections were shown under the microscope which illustrated the points brought out in the paper.

Dr. White would ask the reader what evidence he had that in ringworm and favus a decreased vitality was necessary.

Dr. Robinson thought that it was found in the fact that it was exceedingly difficult to cure these affections occurring in broken-down subjects until the general health was improved.

Dr. White could not agree with the speaker in the importance of depressed general health as a factor in the production of these diseases. He had never seen any necessity for internal treatment in these cases. Where the disease affected the general surface of the body it was readily removed, but where it involved a portion covered with hair it was difficult to cure.

Dr. Piffard agreed with Dr. Robinson that there was a relation between the condition of the general system and the rapidity of development and rapidity of cure of the disease.

Dr. Duhring had always held the view that a particular condition of the epidermis was necessary for the growth of the fungus. The majority of cases of obstinate ringworm that he had seen had been in individuals in poor health, but there were exceptions to this rule. What this peculiar condition of the skin was had not been determined.

Dr. Denslow had recently seen a large number of cases of ringworm of the head and beard, but all the patients were well-developed, muscular subjects. These were cured without internal treatment.

The Structure of the Derma and the Development of Elastic Tissue in it.—Dr. C. Heitzman, of New York, read a paper on this subject. He drew attention to the fact that Stricker had now accepted his (the author's) views concerning the life of basis substance. Dr. Gartner, Stricker's assistant, who was present at the meeting, had brought an electric-picture microscope, by means of which these newly discovered facts could easily be demonstrated to a large audience upon a screen. There were three varieties of basis structure, differing from each other in their chemical constituents—viz., the glue-yielding basis substance proper, producing the spindles within the bundles of so-called fibrous connective tissue; the cement substance between the spindles; and the elastic substance developing along the edge of the bundles in advancing age and in some tumors. All three varieties were traversed by a delicate reticulum of living matter in connection with the protoplasmic cords, that filled the interstices between the bundles in the shape of a comparatively coarse reticulum. Thus it became intelligible that in morbid processes not only the protoplasm, but also the basis substance, participated in an active manner. After the liquefaction of the solid fields of glue-yielding basis substance the bundles were directly transformed into inflammatory corpuscles, from which started every physiological and pathological new formation.

A Case of Multiple Myomata of the Skin accompanied with Severe Pain was described by the President. A. B., aged thirty-six, married, with healthy children and good family history, had never had syphilis. His present trouble began a year ago. Changes in the weather produced pains in the parts which had since become affected. To relieve these, firm pressure was made with the hand. Between the paroxysms, pain was not produced by pressure. Afterward the lesions presented themselves. The pains still persisted, recurring at intervals varying from a day to a week. The attack lasted two or three minutes and did not return the same night. The growth was situated on the right side of the back, in the mid-dorsal region, and the course of the growths was obliquely outward. There were one or two of the elevations on the left side. Three of the growths were as large as peas. The others were small. The epidermis was not abnormal. On passing the hand over these growths, there was no hyperæsthesia, but, on deep pressure in the neighborhood of the larger masses, the patient sank moaning to the floor. One of the larger growths was removed, and microscopical examination showed it to be composed of smooth muscular fiber. From a clinical standpoint, the case bore a close relation to the cases of neuroma which had been reported. The author concluded that certain new growths in the skin, accompanied with severe pain, might be widely different histological structures. We were not justified in assuming that a painful tumor of the skin was a neuroma or fibro-neuroma simply from its clinical history, without a microscopical examination.

An Unusual Case of Tylosis of the Hands was related by Dr. R. S. Morrison, of Baltimore. The patient was a negro, aged thirty-two, muscular, well developed, and apparently healthy. He was a fireman of a steamer and had occupied this position for ten years, shoveling coal with the right hand grasping the upper portion of the shovel and the left hand sliding up and down the handle. Two fingers of the left hand were worn off to the second joint, while the other two were going in the same way, the nails having nearly disappeared. On several occasions he had drawn pieces of bone from the fingers. There had been no pain at all connected with the affection. On this hand there were some large blisters, beneath which there were red granulating surfaces, which were painless. There was no history nor evidence of syphilis. Specific treatment had been used without effect. The man obstinately refused to give up his work, so that little could be done in the way of treatment.

Dr. Tilden thought there was a good deal of resemblance between this case and cases of perforating ulcer of the foot, and this would lead us to suspect a nervous element.

Dr. Wigglesworth remarked that it resembled anæsthetic leprosy in some respects, but differed from it in other points.

Dr. Morrison considered it a strictly local affection from the fact that the hand which was most exposed to rubbing and to the heat of the furnace was the one most affected.

Dr. Duhring would be inclined to consider the callosities a secondary condition. The occupation probably had something to do with the aggravation of the disease, but, if the occupation had been different, there would probably have been a similar change. He would regard it as dependent on some deep change in connection with the nerves, similar to what occurred in perforating ulcer of the foot.

Dr. Morrison could hardly admit that it was an affection of the nerve in the first place. It might be that the continued congestion of the skin dependent on the man's occupation had produced changes in the nerves or other part, which culminated in this affection. Referring to the literature of the subject, he had found similar cases attributed to mechanical irritation.

The Relations of Herpes Gestationis and certain other Forms of Disease to Dermatitis Herpetiformis.—Dr. Duhring read a paper with this title. Attention was briefly directed to the author's previous articles on dermatitis herpetiformis, and to a paper showing its identity with the impetigo herpetiformis of Hebra; also to a preliminary note on the relation of this disease to herpes gestationis and other similar forms of cutaneous disease, read before the association at the last meeting. The object of the present communication was to prove the identity of so-called herpes gestationis with a vesicular variety of dermatitis herpetiformis, and to show that the term herpes gestationis was a misnomer, the affection being found in men as well as in

women. Secondly, that certain other so-called forms of herpes—such as herpes pemphigoides, herpes vegetans, herpes pyæmicus, etc., as well as certain cases regarded by the reporters as peculiar forms of pemphigus—must be viewed as examples of this disease; and, finally, that instances of the same affection were also met with in literature under the title of hydroa and under divers other captions. Numerous cases from English, French, and German literature were cited. The paper was to be looked upon as supplementary to the preliminary note referred to, and embodied the results of considerable research into literature. If the views put forth proved to be correct, a great deal had been gained for dermatology in bringing these peculiar forms of disease together.

Dr. White thought that the term dermatitis herpetiformis was a misnomer. The disease should be called dermatitis multiformis. The herpetic element was often wanting.

Dr. Robinson agreed with Dr. White that the term dermatitis herpetiformis was too restricted, but would prefer some term which did not indicate the pathology, until the disease was better understood.

Dr. Hyde said there were reasons why he would disagree with the last speakers. The term herpetiformis was preferable, if for no other reason, because it was suggestive.

Dr. Fox showed a photograph of a case which might be mistaken for dermatitis herpetiformis—namely, erythema multiforme. This disease should be placed in strong contrast with dermatitis herpetiformis.

Dr. Duhring said the name dermatitis herpetiformis had been adopted because it seemed the least objectionable. The herpetiform character of the disease was to his mind characteristic. The term dermatitis multiformis was already employed to designate a form of skin trouble.

Mycosis Fungoides.—Dr. Tilden described the case of a man aged twenty-eight years when he came under observation. Three years before, several red, desquamating spots had been observed on the elbows. Several months later erythematous spots, accompanied with pruritus, were noted. These lesions retained a dry, scaly character. There were no vesicles or pustules. At the end of a year several red nodules appeared on the face and throat. These, however, disappeared. Afterward a small papule appeared on the right thigh, and increased in size. From this there exuded a thin fluid. This was followed by the development in many parts of the body, particularly the axillæ, groins, and neck, of similar lesions, in some cases reaching the size of a hen's egg. After a time there was superficial erosion of some of the tumors, but these excoriated tumors remained firm in consistence. Some of the masses which were covered with epidermis were soft, but there was no evidence of the formation of pus. There was also indolent enlargement of the lymphatic glands. The general health continued good. The patient passed from observation, and died at the end of three years and a half. The report of the microscopist who examined the tumors was read. His opinion was that the growths consisted of the formation of lymph tissue in the corium. Reference was then made to the literature of the subject, and the various cases, some thirty in number, were given. Sections of the growth were also presented for examination.

Dr. White said that this patient had been under his care during the last stages of the disease, and presented the changes which had been described. Some of the larger growths disappeared. During the last months of his life the man was taking arsenic. Death resulted from the occurrence of diarrhœa.

Dr. Rohé said that four years ago he saw a case of what he thought was the same affection. A man, sixty-two years of age, had a multitude of these tumors. Several had been extirpated before he came under his care, but there was recurrence with this fungoid appearance. The man was given arsenic, but he died from exhaustion. No autopsy could be obtained. As far as could be detected, there was no affection of the liver or spleen.

Dr. Morrison had seen a similar case, which was diagnosticated as multiple sarcoma of the skin.

Dr. Fox said that one or two similar cases had been seen in New York. Should one come under his care, he would try the effect of chaulmoogra oil. Judging from its effects in other cases, it should be useful.

The President said that in a case of alveolar sarcoma which he had reported, the disease had existed fifteen years, but the clinical features were about the same as they were years ago. There was marked enlargement of the lymphatic glands. The general condition was good.

Dr. Heitzman said that the description of the microscopic appearance and the examination of the specimen confirmed him in the view that this was a case of lympho-sarcoma.

Dr. Sherwell, to show the amount of involution that might take place, would refer to a case of melano-sarcoma under his care. The man was treated with arsenic, mercurials, etc. After six months' treatment, the tumors had almost entirely disappeared. There was not the slightest evidence of syphilis.

Dr. Fox had seen chaulmoogra oil used in a case of leprosy. There was now not a trace of leprosy, except the contraction of the fingers, which was, however, a secondary condition. It had failed in many cases, but a trial of it was justified in the chronic inflammatory affections referred to.

Urethral Irritation in the Male as a Cause of Certain Neuroses and of Acne was the title of a paper by Dr. Denslow, who first gave a brief review of the cases of contracted meatus reported by Dr. Otis. He then gave an account of a number of cases that had come under his observation in which there were reflex conditions associated with morbid states of the urethra—such as contracted meatus, stricture, and excessive sensitiveness of the prostatic urethra. In these cases removal of the urethral trouble produced an alleviation or cure of the affection to which attention had been directed. He also reported four cases of severe acne in which the same treatment had been followed by marked improvement or cure. In some of the cases ergotin was also employed. He simply reported the cases as so many observed facts, and did not express any theory. He would keep the cases under observation, and at a subsequent meeting give a further report.

Dr. Sherwell thought that acne was largely a reflex disorder, but was not in the habit of introducing a sound in every case of acne. He produced good results with other measures. He believed in the action of ergot in connection with local applications, especially in females.

Dr. Hyde thonght that many of these patients with urethra trouble associated with acne had probably been taking balsamic preparations for some time, and, as a result, had acne.

Dr. Denslow said that in all the cases reported the acne had existed since puberty. The patients were not hypochondriacs, and they were not masturbators. He was satisfied that no drugs had been used by any of them.

Friday's Proceedings.

Remarks on Electrolysis and other Practical Topics was the title of a paper by Dr. Heitzman. The reader spoke very highly of electrolytic epilation. For this purpose he used the Leclanché battery. He employed a needle devised by Leiter, of Vienna, which permitted the depth to which the needle penetrated to be measured. He had had good results from electrolytic destruction of dilated blood-vessels in the face, but less satisfactory results in the treatment of port-wine marks, a perma-

nent cure of which was only exceptionally attainable. Sodium ethyl had been highly recommended for the destruction of angioma of the face, but it was in no way superior to nitric acid. The author maintained, after observing two hundred cases of falling of the hair caused by seborrhœa, that the method he recommended in 1876 gave fair results. This was the application of a ten- or twenty-per-cent. ointment of crude oleum rusci in vaseline and paraffin. For the removal of freckles he used an ointment recommended to him by Wertheim, of Vienna:

White precipitate, Subnitrate of bismuth,	each.....	1 drachm;
Glycerin ointment.....		1 ounce.

This was to be applied in a thin layer every other night, and in from four to six weeks the result would be found to be highly satisfactory. As to the permanency of the cure he was unable to state. In regard to the reappearance of hair after removal by electrolysis, he considered it to be due to the growth of the fine hairs, which was increased by the transfer to them of the nutrition which should have gone to the hairs removed.

Dr. Hyde said that, in the removal of hair by electrolysis, the question was not what the result would be at present, but what it would be in the future. Electrolysis produced a hyperæmia, which tended to stimulate the growth of the remaining hair. He had found the rectified oleum rusci very valuable.

Dr. Fox had used nitric acid for angioma, making the application in the form of small dots, a quarter to half an inch apart, with great advantage. In one case in which a nævus occupied half the body he had used this treatment with much success. In regard to the return of the hair after electrolysis, if the needle was carefully inserted and gentle traction was made on the hair, that hair would not return. In some cases there was a constant increase in the downy hairs from some cause, but these were exceptional cases. He did not think that the removal of hairs increased the growth of others. In the case of a young woman with a heavy beard he had removed, by actual count, eight thousand hairs. This process had required two or three years. Since then it had been necessary to remove only a few dozen hairs.

Dr. Robinson had used a similar ointment for the removal of freckles, but its effect had been only temporary. He thought that the growth of the remaining hairs was increased by the removal of a portion.

Dr. Wigglesworth had for the past fifteen years used the following ointment, which was almost identical with that mentioned by Dr. Heitzman:

White precipitate, Subnitrate of bismuth,	each.....	10 parts;
Vaseline.....		100 "

The President had performed the operation of electrolysis for ten or twelve years, probably longer than any other member of the association. He used the irido-platinum needle, which had the advantage of being bent and was not likely to pass through the follicle-wall. The moment the follicle was entered there was an escape of sebum. One case, that of a woman with a heavy black beard, had been entirely relieved. Electrolysis with a fine needle afforded a method of getting rid of freckles. The plan was to dot the surface covered by the freckle with the needle.

Dr. Heitzman said that the percentage of recurring hairs was greater in some situations than in others. In the submaxillary region it was greatest.

Syphilitic Reinfection.—Dr. Taylor read a paper on this subject. He first referred to the literature, and gave a brief review of the authentic cases on record, with the names of the reporters. The number of cases previously reported was between thirty and forty. To these he added the histories of three more. A fourth case had been observed by him, but, as the complete history had not been prepared, it was not given.

Case I.—A barkeeper, aged twenty-five years, was first seen in 1868, suffering with gonorrhœa. Three years previously he had had indolent enlargement of the lymphatic glands in the groins. Examination showed the presence of lymphatic enlargement in certain regions. Inquiry into the history showed the existence of a chancre three years before, which had been slow in healing. About two months later he became sick and suffered with a roseolous eruption, sore throat, falling of the hair, and rheumatic pains, worse at night. Under treatment he improved, but afterward exhibited a papular eruption. He was then seen by the late Dr. Van Buren, who pronounced the case one of syphilis and ordered mercurial treatment. He recovered after two years, but of his own accord continued the treatment two years longer. He then remained well until the attack of gonorrhœa. In February, 1870, he again appeared, presenting a typical indurated chancre on the pubes. It presented every evidence of a primary infection. Afterward a papular syphilide appeared over the body, there were several mucous patches on the pillars of the fauces, and the throat was red and swollen. The joints soon became the seat of nocturnal pains. The patient also presented a form of syphilitic epididymitis. Under mercurial treatment there was some improvement, but a year later there were some tertiary manifestations. By 1874 he seemed very well. During the next three years there were no evidences of syphilis, but he continued the "mixed treatment." In the autumn of 1882 it was learned that his good health had continued and that he was the father of a healthy child. The child was examined, and no evidence of hereditary syphilis was detected.

Case II.—In June, 1873, the patient had a typical indurated chancre, followed by distinct secondary symptoms, which disappeared under treatment. He then passed from observation. In February, 1874, he presented several ulcero-tubercular lesions on the outer aspect of the forearm. He then remained under treatment six months. In January, 1875, he had spots of thickening of the periosteum of both tibiæ. He was again treated with benefit. In June, 1876, there was a typical indurated nodule on the prepuce, from which indurated lymphatics extended to the inguinal lymphatic glands. The incubation of this sore had lasted about twenty days. This was followed by malaise, sore throat, and swelling of the post-cervical and epitrochlear glands. Over the body and arms there was a fine mottling of a light pink color. The patient then went to Europe and was not seen until March, 1885, when it was learned that the symptoms had been well marked, and that he had been under treatment for them by several Continental physicians.

Case III.—A man, forty-one years old, had had a typical indurated chancre in 1874. There had been inguinal adenitis, followed by roseola, falling of the hair, and subsequently severe iritis. He was treated with mercury. In February, 1882, he returned with a typical hard chancre. In April he became sick, having rheumatic pains and a mixed erythematous and papular eruption. In May iritis again appeared. In 1883 he had a late secondary rash.

These cases were reported with the object of throwing some light upon the natural history of second infections of syphilis. In all of them relapsing indurations had been carefully excluded.

Observations on the Oleates.—Dr. Stelwagon read a paper on this subject. In regard to the chemistry and preparation of the various oleates, both as to their manufacture by the direct combination of the acid with the base and by double decomposition, almost, if not entirely, as much could be found in the

English translation of Gmelin's "Handbook of Chemistry," published in 1866, as in the writings of the past several years. Of all the oleates, those of mercury, zinc, bismuth, and lead had a place in the treatment of diseases of the skin; and, in view of their costliness, the seeming unavoidable frequency of badly made preparations, the disagreeable oleic-acid odor, and the irritation so frequently observed after their use, it was probable that of these four only the mercuric oleate promised to retain a permanent value. This last was especially valuable in ringworm of the scalp, but for inunctions in the treatment of syphilis it was of doubtful utility, as it was questionable whether it was absorbed. Oleate of copper, which had been so highly recommended for ringworm of the scalp, was not comparable in that affection to oleate of mercury or to tar and sulphur preparations.

Dr. WIGGLESWORTH had practically renounced all oleates except the oleates of zinc, lead, and mercury as parasiticides.

Dr. DUHRING's experience with these preparations had been in accord with that of the reader of the paper. He had employed the oleate of copper in varying strengths in thirty or forty cases of ringworm, but it had seemed to exert no influence whatever. But they had been obstinate cases. Other methods of treatment had afterward been tried, and they were finally cured. As to its efficiency in acuter forms of ringworm, he was not prepared to speak.

Dr. HEITZMAN had tried the oleate of copper in chronic cases of ringworm, without any result, but in the acute cases it cured after a time. It was not so efficient, however, as the preparation recommended by Dr. Taylor—four grains of bichloride of mercury to the ounce of tincture of myrrh.

The PRESIDENT had almost entirely discarded the oleates. In some recent cases the oleate of copper had seemed to be successful, but in chronic cases it had entirely failed.

A Case of Syphilitic Aphasia and Paraplegia followed by Death, with an Account of the Autopsy.—Dr. DENSLOW read a paper the object of which was to put on record a case in which an autopsy had been obtained in early syphilitic cephalalgia. The patient was seen in consultation April 29, 1885. Two months previously he had begun to suffer with severe headache, worse at night. There was also a papular eruption. He acknowledged the existence of a sore six months previously. Iodide of potassium with chloral had been given. Two weeks later the patient was free from pain, but it returned in one month and he stopped taking medicine. Iodide of potassium was again given, with the effect of relieving the pain. Aphasia and paraplegia then developed, and the patient died four days later, within nine months of the initial lesion. At the autopsy, the dura mater, along the superior longitudinal sinus, was thickened and adherent. There were numerous small gummata in the pia mater, situated along the right border of the longitudinal sinus and extending back to the fissure of Sylvius. The pia mater exhibited evidences of simple acute inflammation.

NEW YORK OBSTETRICAL SOCIETY.

Meeting of March 3, 1885.

Dr. E. NOEGGERATH in the Chair.

Drainage-Tubes.—The CHAIRMAN showed a series of drainage-tubes for use after laparotomy. The first one was the straight glass tube known as Tait's, the second was Sims's rubber tube, and the third was one which Dr. Noeggerath had himself used on one occasion. The large curved glass tube used by Hegar was next shown. Its wall was perforated in numerous places at its lower portion, the openings being not above 1 mm. in diameter. The advantages of the instrument were its large size, which not only admitted of free drainage, but allowed a reflector to be passed into the tube so that the neighboring parts could be explored. The lateral openings permitted the fluid to enter the tube readily from all sides. They should not be too large, as there was danger of the intestines becoming engaged in them.

The CHAIRMAN also gave an outline of the after-treatment of Hegar's ovariotomy cases. For the first twenty-four or forty-eight hours the patient received only ʒ ss. of cold water every hour, then ʒ ss. of sour wine every hour for the next twenty-four hours.

Dr. J. B. HUNTER asked in what cases such large drainage-tubes were indicated, and how the inference could be drawn that there would be so much fluid secreted as to require one.

The CHAIRMAN replied that they were used in cases in which there were extensive adhesions, not only to the parietes, but to the abdominal viscera. He admitted that the necessity for their use was rare.

Dr. B. McE. EMMET asked if it was not difficult to close a wound after the introduction of so large a tube.

The CHAIRMAN replied that, on the contrary, the wound contracted so rapidly that a smaller tube must be introduced immediately after the withdrawal of the large one.

Dr. W. G. WYLIE thought that, judging by his own experience, the cavity would only drain for a short time. He had sometimes found it necessary to move the lower end of the tube about to break up adhesions.

Dr. B. F. DAWSON thought that the excessive outpouring of fluid to which the chairman had alluded might be the ordinary peritoneal secretion, which, being innocnous, did not require to be drained away.

Dr. HUNTER said that he had used even smaller tubes than Tait's, and had never found any difficulty in removing all of the fluid by means of a syringe. He preferred straight tubes, since they could be carried down to the very bottom of Douglas's pouch.

Dr. WYLIE also favored the use of small tubes.

Dr. W. M. POLK recalled a case, related to him by Dr. Thomas, in which a hernial protrusion of the intestine took place through one of the lateral openings in a drainage-tube.

Hysterectomy for Fibroma.—Dr. H. D. NICOLL presented a fibroid tumor with a portion of a uterus removed by Dr. Thomas at the Woman's Hospital. The patient gave a history of profuse hæmorrhages. The diagnosis of interstitial fibroid located in the posterior uterine wall was made, and Dr. Thomas resolved to perform a myomotomy. The usual incision was made through the abdominal wall, the uterus was rolled out of the cavity, and its neck was constricted with an instrument devised for this purpose, consisting of two semicircular pieces of steel, provided with handles, something like a pair of tongs. The tumor was found to occupy the posterior wall. An incision was made down to the capsule, which was opened, and the tumor was readily enucleated. On relaxing the pressure of the clamp the hæmorrhage from the wound was so profuse that Dr. Thomas saw that it would be necessary to remove the entire uterus. This was then accomplished, the stump (which was long and rather narrow) being secured with Dawson's clamp. The patient's condition had been perfectly satisfactory. Dr. Thomas was for a time under the impression that he was the first who had followed this method of enucleation, but he now yielded the priority to Dr. Hunter.

Dr. P. F. MUNDÉ said that Schröder had first performed this operation.

The CHAIRMAN was of the opinion that Martin was entitled to that honor.

Dr. HUNTER asked if Martin used drainage.

Dr. Mundé replied that he drained the wound through the vagina in cases where the growth extended down into the pelvis or between the folds of the broad ligament.

Dr. B. McE. Emmet asked concerning the relative merits of myo-hystereetomy and removal of the ovaries as a means of relief from hæmorrhage resulting from the presence of uterine fibroids.

The Chairman said that the question was not yet settled, English surgeons being rather in favor of oöphorectomy, while the Germans preferred hysterectomy.

Dr. Dawson, referring to the fact that his clamp had been used in this operation, said that his idea in devising it had been: 1. To secure perfect constriction of the stump by an instrument which should compress it into the form of an ellipse. 2. To have a smooth lower surface which should allow the external wound to heal perfectly and to become perfectly adherent to the stump.

Dr. Hunter said that he preferred to transfix the stump with needles and to encircle it with a rubber ligature.

The Chairman thought that by the use of the clamp the adhesion of the skin, as well as of the peritonæum, to the sides of the stump was secured.

Dr. Dawson explained that he removed the clamp after a few days and substituted for it transfixion with needles.

Salpingo-oophorectomy.—Dr. Hunter presented the following specimens: 1. A specimen of double hydrosalpinx, removed at an autopsy from a case of cancer of the omentum, the patient having died from fatty heart several days after the operation. 2. Pyosalpinx (private case). The patient was a young single woman who had suffered with extreme dysmenorrhœa. She had been completely relieved by the operation. 3. A case at the Woman's Hospital. A married woman who had suffered greatly from menorrhagia and metrorrhagia, symptoms which disappeared after operation. 4. In this case the operation was done for dysmenorrhœa, and was easy. Another case was also related, but the specimen was not shown. The patient had had severe hæmorrhages. On examining her, Dr. Hunter thought that he detected a small tumor behind the uterus, and also an enlarged tube. At the operation a small ovarian cyst was found upon one side, with an enlarged tube. During the attempt to remove it, the tube ruptured, and a quantity of fœtid pus escaped. The opposite tube was so firmly bound down by old adhesions that it was removed with great difficulty. There was a good deal of hæmorrhage, which was not checked until much time had been spent. In the search for the bleeding points the operator was greatly assisted by the combined use of a cylindrical speculum and the small electric light which had been designed for this purpose. The patient developed septic peritonitis, and died on the sixth day.

Dr. Hunter stated, in general, that it was his custom to introduce a drainage-tube if there was much hæmorrhage, but it was soon removed. In regard to the symptomatology of pyosalpinx, he said that an important point was that the patient complained of pain just *before* her periods, excessive flow, and a subsequent discharge of fœtid pus. In one case he had even seen this purulent fluid escaping from the os. He concluded with the remark that he now used spray in the operating-room, although it was not thrown directly upon the wound. This was a necessary precaution in the presence of a miscellaneous crowd of spectators; he also endeavored to have his ligatures perfectly aseptic.

Dr. Mundé mentioned a case which showed the difficulty of making an accurate diagnosis before operation. A patient was sent to him with a history of recurrent attacks of peritonitis. On examining her, he thought he detected an ovoid, fluctuating mass upon the right side on the left side nothing could be felt but a diffuse swelling. On opening the abdomen, nothing could be differentiated; the pelvis was filled with an inflammatory deposit, in which both ovaries and tubes were indistinguishable. The only thing which could be done was to ligate the broad ligament in two places by carrying a threaded needle deep into the pelvis and removing the mass by burning it through with Paquelin's cautery. The patient made a good recovery. Dr. Mundé admitted that there were cases in which it was possible to make the diagnosis of enlargement of the tubes, but it was frequently quite impracticable. He had at the time a patient under treatment, on examining whom for the first time he had discovered a sausage-shaped mass situated on the right of the uterus. He aspirated this tumor through the vagina and withdrew about ʒ iij of clear fluid, in which was found cylindrical non-ciliated epithelium. This was undoubtedly a cast of hydrosalpinx.

Dr. Wylie said that it was not necessary to make such an exact diagnosis. If a patient had been under observation for some time, and the subjective symptoms were such as to warrant an operation, he did not disturb himself about the exact condition of the tubes. But, he added, it was possible in many cases to so clear up the inflammatory deposits by a course of treatment with boro-glyceride tampons that the diagnosis could be positively made. He believed that many of the so-called cases of "thickening in the broad ligaments" were really cases of enlarged tubes.

B. McE. Emmet, M. D.,
B. F. Dawson, M. D.,
H. C. Coe, M. D., *ex officio*,
Committee on Publication.

Miscellany.

The International Medical Congress.—Professor Hansen-Grut, of Copenhagen, who was president of the ophthalmological section of the last meeting of the Congress, and took an active part in the affairs of the organization, has written the following letter to a New York physician:

"I am sorry you have so much bother about the Congress. The spirit that is at the bottom of the dispute is to me a proof of such exclusiveness as I should not have expected to find in your country. I will answer to your question:

"1. That the controversy about codes was never thought of, as we have nothing resembling your codes of ethics.

"2. The invitation was decidedly given for the *whole* medical profession; none of us thought of, or even mentioned, the American Medical Association.

"3. The *only* qualification required was, that the member be a *legally acknowledged* medical practitioner in his country. *Our* homœopathists who were legally acknowledged practitioners (Dr. Siemsen-Ferish and others) were actually members, and undisputed members, of our Congress.

"I have sent your letter to Prof. Lange, who will, no doubt, corroborate my statements. To my knowledge, he has already had similar questions addressed to him from America, and answered them in the same way as I have now done.

"The way across is long, the fear of the sea is strong. I do therefore firmly believe that it is injurious to the interests of the Congress to have too many restrictions put for admittance."

The "New Orleans Medical and Surgical Journal" says:

"Since the August issue of the Journal there has been but little change in the controversy over the organization of the American meeting at Washington in 1887. The disagreement remains as irreconcilable as ever.

"The situation is certainly without precedent, and all brought about by the action of a very small majority of a very small meeting of the American Medical Association, an organization which itself represents only about one twentieth of the American medical profession. The association has unjustly been held responsible for the action of scarcely one fourth of its members, and on this account has suffered severely of unfriendly criticisms. We trust that these criticisms, instead of impairing the usefulness of the association, will rather enliven the interest of many of the older and more sturdy members whose conservative presence at the last meeting surely would have averted all our recent troubles; very likely the new committee would never have been created. However, let us speak of the realities.

"No sooner was the new committee organized than it evinced the temper of the resolution under which they were appointed. They began to revise, alter, and amend the work of the original committee with a vengeance. They announced a new plan of organizing the Congress, based upon an illiberal policy, which, for one reason and another, excluded from membership on the sub-committees and sections a number of names of international prominence. There was at once dignified opposition to the course of the committee, which was all the more determined because of a lack of respect for their authority, owing to the unpardonable impropriety of the proceedings under which they were appointed. Numerous resignations from the sub-committees and sections have followed in rapid succession. So far, upward of one hundred and twenty names, all told, have been either dropped by the committee or voluntarily withdrawn from all official connection with the Congress. Many of these names are classical in the history of American medicine, and their disaffection alienates from the coming Congress the friendly interest of our more distinguished *confrères* abroad, without whose support the American meeting can not succeed. Our brethren from over the sea are very emphatic in expressing their views of the situation. Their criticisms are sharp and well directed. In the pages of those solid contemporaries, 'The Medical Press,' the 'Lancet,' and 'The British Medical Journal,' we can see ourselves as others see us.

"Public professional opinion in the United States demands a truce of all our domestic differences and the organization of the Congress upon a broad and liberal basis, recognizing the representatives of American medicine, those so considered at home and abroad, regardless of all local code, or purely personal issues, which are so entirely irrelevant to the purposes of the international body. We say *demand* advisedly, for the sixty odd thousand American physicians, in whose name (whether right or wrong) the invitation was extended and so accepted, as well as the foreign gentlemen of our own profession, invited to our shores, surely have some rights entitled to respect.

"If the committee continue much longer in disrespect of those rights, with as little progress in organizing the Washington meeting, then the officers of the Congress may see proper, as intimated in some of our foreign exchanges, to recall acceptance of the American invitation in favor of Berlin, or some other European medical center, where, as the 'Lancet' says, 'the medical profession will not find it impossible to combine for international purposes.' The stigma upon us of such an occurrence the present generation would not outlive.

"The committee must surely by this time realize the impossibility of organizing the Congress in further pursuance of their present policy. As gloomy as the outlook appears, we yet hope that at the coming meeting of the committee in New York, on the 3d of September, some way may be found of reconciling all our differences and organizing the Congress upon a high and broad basis, upon which we can all stand for the time without jostling and jarring.

"NOTE.—Since the above went to press, we have received a circular entitled 'The Pennsylvania Physicians Indorse the Code of Ethics,' which demands a word from us. The circular is signed by a number of the ex-presidents of the State and various county medical societies of Pennsylvania, and others, who indorse the action of the American Medical Association at New Orleans, as well as the action of the new committee at Chicago, and call all this sustaining the code of ethics. This would intimate that those who have not approved of the action of the American Medical Association or its Chicago committee, on the subject of the International Medical Congress, do not indorse the code of ethics of the association. We desire to place ourselves right in this matter. This journal indorses the code of ethics of the American Medical Association, but emphatically disapproves of the action of that body regarding the meeting of the International Medical Congress. While we support the code of ethics, we do not believe that it was expedient or right to inject that code into the organization of an International Medical Congress. We believe that the organization of the Congress, as proposed by the original committee, ought to have been accepted, or at least should have been less radically modified. We do not take sides with the new-code physicians of New York or elsewhere, but we sincerely believe that it was inexpedient and unwise to exclude them solely on account of their ethical sentiments. We are advocates of the national code, and shall exert our influence to uphold it; but we favor no plan of organizing the International Medical Congress that is not high and broad and liberal, in full accord with the spirit of the international body, and entirely acceptable to the better sentiment of the home profession, as well as to the guests invited to our shores.

"Under the circumstances, having foreknowledge of the views of many of our foreign brethren on this subject, we should be more consistent with the principles enunciated by the Chicago committee, under direction of the American Medical Association, if we should frankly acknowledge our mistake and withdraw the invitation we have extended. Either do this or meet them in the spirit they demand."

The "Cincinnati Medical Journal" says:

"It was hoped that the enlarged committee of the American Medical Association, at its Chicago meeting, would so shape its deliberations as to escape the imputation of being actuated by sinister motives. The further we get away from that meeting, however, and the more we learn of its inside workings, the more are we convinced that personal pique, local jealousies, sectional prejudices, college hatreds, and clique antipathies, were more responsible for the changes made than were any considerations of professional morality or ethical punctilio, or what should have been first, foremost, and alone, a desire to strengthen the Congress by bringing to the front our ablest and most representative men."

The "Chicago Medical Journal and Examiner" says:

"In the organization of the Congress, the same rules should govern in the next that have obtained in the past. No distinction should be made between the foreign and the American members. The fact should be distinctly kept prominent that it is not a delegated body. It has not been in the past; there is no valid reason why there should be any effort to make the next one such. There should not be two or more classes of members. All must meet on the same plane—with equal privileges, equal duties, and equal responsibilities. Let all local ethical questions be eliminated. The foreign representatives expect and demand this, and such is their right. There may be honest differences of opinion, in our own country, on certain points of principle and policy, but there can be no valid reason for thrusting them, or their effects, upon foreigners who may come here. Sight should not be lost of the fact that science and humanity are the objects for which these congresses convene, and that all matters of selfishness and partisanship should be subordinated thereto.

"As our faith, as a profession, was pledged, when our invitation was accepted, to do all in our power to make a success of the Congress, we can not do less. Everything that might conflict therewith and diminish the prospect of such success must be kept in abeyance."

The "Maryland Medical Journal" says:

"In view of the fact that the American Medical Association committed an unjustifiable and unnecessary blunder in authorizing a new committee to organize the preliminary arrangements for the Ninth International Medical Congress, we had hoped that this committee, after the experience of its late meeting at Chicago, would recognize the absurdity of its position and gracefully decline to take further steps looking to an arrangement for the Congress.

"It has seemed to us that the action of this committee has been so universally condemned, and its resignation so loudly insisted upon by the almost unanimous voice of the profession, both in this country and in Europe, that it would not have the boldness to proceed with its work in face of such outspoken opposition. At first we were disposed to lay

the entire blame for the present muddle of the affairs of the Congress upon the shoulders of the association. We assumed that this committee was acting under the instructions of the association, and, therefore, in accordance with these instructions, had performed the work assigned to it in as mild a way as was to be expected under the circumstances which had called it into existence. After the utter failure of its efforts at Chicago, and in view of the disturbance its action has brought about, we have felt that this committee was in duty bound to decline any further participation in the work of re-organization of the Congress. Having so signally failed at Chicago, we are unable to understand upon what ground it can hope to be more successful in its future undertakings. From a circular which has recently come into our possession, we fully recognize the part which this new committee will attempt to perform. Bracing itself up under the issues of the 'code,' this committee will urge the re-organization of the Congress upon this platform. It proposes to stand by this issue alone, and to distribute its loaves and fishes to those only who obligate themselves to support the national code of ethics.

"We have already shown the absurdity of this issue as applied to the organization of an International Medical Congress. We must insist that this attempt of the association and of its committee to hoist this issue into prominenee is an insult to the medical profession throughout the entire world, and an insult to scientific medicine wherever it is taught and practiced. To attempt to enslave individual opinion in this manner is a stab at ethical principles which will penetrate into the very heart of the national code of ethics and create a prejudice against these time-honored observances which the association can not stay. The association and its committee is standing on dangerous ground, and is inviting a controversy and a strife about medical ethics which will surely plunge the association into the deepest grief. The American Medical Association is yet an infant organization. It has not the power to dictate its terms to the intelligence of the profession in this country. With a membership of less than three thousand it is assuming prerogatives and asserting principles which may endanger its very existence.

"But, after all, this cry of the 'code' has a tamer significance than a easual observation would indicate. We have already noticed the fact that the 'code' issue has been repudiated by the very best scientific minds in this country and in Europe. The present committee has caught on to this issue as a possible popular wave to ride into high official position and authority.

"In our opinion it cares but little for the success of the Congress apart from the popular conception of such an organization. Its proposition to organize a Congress simply means a jolly good meeting, with code for breakfast, scientific medicine for lunch, and the American Medical Association for a sumptuous dinner. On this mixed diet our foreign friends are to be hospitably banqueted, and, if enough foreign guests will not come across the waters to partake of this repast, the jolly feast will be enjoyed all the same by the code adherents and their friends. Indeed, the whole outlook for the Congress is utterly ridiculous and absurd. The profession in this country may well cry shame over its present humiliation. Who can look on and not blush over such an arrangement as is proposed by our National Medical Association in honor of a great and influential body of scientific workers? Who can indorse the work of a committee or accept its proffered honors when one has considered the fact that it would gauge scientific opinion and practice by a standard of conduct which is applicable only to the most ignorant or unprincipled members of the medical profession? The empire of science is not bounded by the restrictions of narrow opinions and prejudices. It demands liberty of action and conduct, and it can only make large and enlightened progress when endowed with these functions.

"The effort of our National Medical Association to impose upon a Congress of scientifie men absurd rules of ethical conduct recalls to mind the narrow prejudices of the middle ages, when men were punished for asserting that the sun stood still, or that the world was not made in six days. In the last quarter of the nineteenth century will the rank and file of the medical profession tolerate such narrow-mindedness? We believe not. This utter absurdity of the association will surely reach upon its unwise and impious head."

The New York Polyclinic.—We learn that during the sessions of 1885–1886 there will be fifteen clinics in gynæcology each week, including operations at Mt. Sinai, Bellevue, St. Elizabeth's, and the Woman's hospitals; six clinics in the department of diseases of children; fourteen surgical clinics, including operations at Mt. Sinai, the German, and St. Elizabeth's hospitals; six, each, in diseases of the skin and of the mind and nervous system; eight in physical diagnosis, including ward lessons at Bellevue Hospital; eight in diseases of the eye, including operations at Mt. Sinai and the German hospitals and the Manhattan Eye and Ear Hospital; four in diseases of the throat and nose; two in diseases of the ear; and four lessons and clinics in obstetrics—making a total of seventy-three clinics every week. The laboratory of pathological histology and State medicine will be open every day and evening up to ten o'clock, and the laboratory of physiological chemistry on Tuesdays, Thursdays, and Saturdays. Special attention has been paid to the outfit for the laboratory, which is fully furnished with all the necessary apparatus for day and evening work in microscopy, bacteriology, chemistry, etc.

THERAPEUTICAL NOTES.

Cocaine in the Treatment of Vaginismus.—Iwow ("Russkaja Medicina"; "Dtsch. Med.-Ztg.") reports the ease of a woman, thirty-two years old, who had been married ten years, and had suffered with vaginismus all that time, in spite of every kind of treatment. She was of slender build, very anæmic, and easily thrown into nervous excitement. The external genitals were normal, as well as the uterus. The vagina was short. Only remnants were found of the hymen. A five-per-cent. vaseline ointment of cocaine was ordered to be rubbed upon the vulva before each coitus. This was late in February, and in April it could already be ascertained that she was pregnant. In May indisposition to coitus supervened, but it yielded to tincture of damiana leaves (twenty drops every two hours). The author attributes the cure of the vaginismus not to the action of the coeaine alone, but in great measure to the moral effect of his positive assurance that it would do away with the pain.

The Choice of Excipients for Topical Applications.—Vigier ("Gaz. hebd. de méd. et de chir.") has written a note on this subject, with special reference to vaseline and some of its congeners, such as *pétréoline, neutroline, carburine, and pétrobaseline*, the last-mentioned of which is the newest of the series and is described as a liquid of fine appearance. Valuable as these hydrocarbons are, the author deprecates their indiscriminate use, and summarizes the principles which should guide prescribers in choosing excipients for external applications. Lard and the oils which resemble it in their action on the skin are the best vehicles for medicaments. The mineral fats, solid or liquid, although having the great advantage of being unalterable, offer a eertain impediment to absorption, retarding it at least. Glycerin prevents absorption, and should never be used as an excipient, but only for its own effect. On the contrary, it should be chosen when it is an object to avoid absorption, as in the use of corrosive sublimate, or to temper the action of irritants, like earbolie acid or arnica. *Pétrobaseline* seems destined to play a prominent part in therapeutics, but its properties, which are curious in some respects, need to be studied further. It does not dissolve boric acid at all, but it dissolves borax. A formula is given for a four-per-cent. solution, made with the aid of gentle heat and filtered.

The Treatment of Chronic Neurotic Diarrhœa.—J. V. Solomon ("Brit. Med. Jour.") remarks that, in hospital and private practice, he is sometimes consulted by women of nervous temperament, on account of a chronic diarrhœa of several years' standing, which has resisted treatment. When he has failed to discover organic abdominal disease he has produced considerable mitigation, and sometimes perfect relief, with the following formula:

Dilute nitric acid	½ drachm;
Battley's *liquor opii sedativus*	1 "
Tincture of gentian	½ ounce;
Infusion of gentian	4½ ounces;
Strong peppermint water, enough to make	8 "

One ounce to be taken three times a day. He is inclined to consider the disorder a neurosis.

Original Communications.

IMMUNITY FROM CONTAGIOUS DISEASES.

BY D. E. SALMON, D. V. M.,
WASHINGTON, D. C.

ALTHOUGH the theory of immunity which I formulated several years ago has been given a prominent place in recent discussions, it was not my intention to take any part in this philosophizing so long as my views were treated with ordinary consideration and fairness. This theory was not developed as a mere piece of speculation to while away an idle hour, nor was its object to excite discussion or controversy. In the course of a long series of original investigations, in which very important facts were discovered, I was brought face to face with this question of immunity, and, in order to continue the investigations intelligently, it became necessary to have a working hypothesis which explained and connected the facts so far as known. The theory of immunity in question was the result of that necessity. It was a sincere endeavor to get at the truth with the facts at hand, and I only desire that it shall stand or fall on its merits. The tendency of working scientists has certainly been very favorable to it; no facts have been brought forward through more recent researches which oppose it, while many strongly confirm it. It does not appear to be so fortunate, however, when it comes in contact with the arguments of those who discard the facts bearing most directly on the subject, and reason from questionable premises and comparisons of doubtful application. A notable example of this may be seen in the article of Dr. J. Romaine Curtiss which appears in the issue of the Journal for July 18th.

Dr. Curtiss scores his first point by reversing the terms of my theory—a rather remarkable piece of carelessness when we find him stating it correctly in a quotation from Dr. Eccles, only a few sentences farther on. "The oxygen theory of Dr. Salmon," he says, "is too narrow a conception for the occasion, and there are no verifications to sustain it. Who can imagine that tubercle bacilli in the lungs can consume the oxygen inhaled so rapidly that there is not a sufficient supply for the lungs? The inhalation of oxygen is found to do harm in consumption as well as many other diseases. If Dr. Salmon's hypothesis is true, the inhalation of oxygen ought not only to cure, but prevent all diseases of zymotic origin." Skipping only one sentence, we come to Dr. Eccles's very clear statement of my theory in these words: "The poison of the microbes intoxicates the cells. Retarded function (of the cells) allows oxygen to increase in the circulation, thus facilitating their gaining a foothold. Recovery is due to the ability of the cells to resist the poison, use up their own oxygen, and so asphyxiate the microbes."

That is to say, of these two contending parties it is not the microbes but the cells which injure their antagonists by exhausting the oxygen supply. Consequently, an artificial increase of the oxygen supply in the tissues would simply give the microbes a better chance in their struggle for existence. The theory here is in accordance with the clinical fact stated by Dr. Curtiss, and is not opposed to it, as he would have us believe.

The next objection is that "Dr. Salmon has not made an estimate relating to the ventilation of the human body with oxygen and the relative amount consumed by the microbes and cells." Here again Dr. Curtiss reasons from a false premise. The most careful chemical investigations show that the liquids of the interior of the body contain either no free oxygen or only a trace of it. The cells of the body which obtain their oxygen from these liquids are, therefore, able to exist and perform their functions with this limited supply of oxygen. In other words, the living protoplasm seems to have such a chemical affinity for this gas that surrounding liquids are kept practically exhausted. The very recent investigations of Ehrlich ("Das Sauerstoff-Bedürfniss des Organismus"), made by a new method and apparently incontestable in their results, confirm this view and place this part of the theory upon a foundation which a wise man will not attack without mature deliberation. Equally careful studies of microbes show that their oxygen requirements are very different, and that some of them require relatively large quantities of free oxygen in order to multiply at all. So far, then, as investigations have gone in this direction, the facts discovered are in accord with my theory of immunity.

The comparison between a combat in which a dog attempts to kill and eat a man in a well-ventilated room and the contest of the microbe and the animal cell in the interior of the body, which Dr. Curtiss next introduces, is one of the most remarkable arguments which it has been my fortune to see introduced into the discussion of a scientific question. It reminds me of the arguments that, only a few years ago, were hurled by certain members of our medical profession against the whole germ theory of disease. Notwithstanding the very positive statement that "the cell and microbe and man and dog present problems of warfare the terms of which are parallel and alike," I can not restrain an equally positive assertion that the comparison is chiefly remarkable for being far-fetched and having no application to the question. There is nothing "parallel and alike" either in the means of attack and resistance or in the conditions under which the two contests are maintained.

Although Dr. Curtiss thinks that the part of my theory which admits recovery to be due to the ability of the cell to resist the poison excreted by the microbe is correct, he does not appear to be able to free his mind from the belief that the contest is, after all, a physical one, and that it consists in the attempt of each to "swallow" the other. That a free, wandering, or amœboid cell might easily "swallow" or take into its interior a microbe, as supposed by Metschnikoff, is freely granted; but that the terms of this proposition can be reversed, and that a microbe with a smooth, rounded body, without external organs of any kind, without an opening in its body to take in its food, without the power of locomotion in the most restricted sense, should make a physical attack upon and "swallow" a cell, certainly requires a free use of one's imagination.

But why does Dr. Curtiss insist that the combat between the man and the dog should be in a "well-ventilated" room in order to be parallel with a combat between a microbe and a cell in the interior of the body? Does not the most superficial knowledge of anatomy and physiology make it apparent that the interior of the body is not well ventilated, that a contest there, instead of being in the open air, is under liquid, and under a liquid which itself is not in contact with the air, and from which the cells of the body are continually drawing the oxygen necessary for their existence? Then, again, the oxygen requirements of the man and dog are substantially the same, and any exhaustion of this element would affect each alike. On the other hand, the oxygen requirements of microbes are very different among different species, some of them requiring an abundant supply, and, as a consequence, a large proportion of these species must have requirements different from the cells of the body.

To make the comparison at all parallel and applicable, it would be necessary to assume that the room in which the man is located is a close one, that he is able to live in an atmosphere that would immediately place the dog *hors de combat*. We must also assume that the dog, even in this partially asphyxiated condition, continues to live and exhales a poison which would gradually accumulate and overcome the man unless its production was so slow that the man would become inured to it before it had been produced in sufficient quantities to overpower him. In the former case we might suppose that the slight ventilation of the room and the smaller amount of oxygen used by the man would in time place the dog in a condition to make an attack. And here, after all our attempts to make the conditions parallel, we fail miserably, for the dog's attack must be essentially a physical one, while the microbe's attack partakes but slightly, if at all, of that character.

Of what use, then, is such a comparison for the elucidation of a question of this nature? Surely any conclusions drawn from it must be unsafe, misleading, or diametrically opposed to the truth.

"It is evident," says the learned doctor, "that we can substitute nitrogen or bile in place of the oxygen of this problem, and do no violence to the sense or the results." Here, again, the conclusion seems to be most hasty and without that consideration which we should expect in discussing a question of this importance. A moment's thought would have convinced our able critic that, if the multiplication of microbes is to be prevented by withdrawing an element from the liquid in which they exist, it is a necessary condition of the case that the element should be one *essential* to the growth and multiplication of the germs. As a matter of fact, neither free nitrogen nor bile is essential to such growth and multiplication. The germs of various contagious diseases can be and have been cultivated where neither nitrogen nor bile exists; but all microbes that have been carefully studied and which produce diseases that are followed by immunity, so far as I have been able to learn, require a certain amount of free oxygen.

Finally we are told: "Dr. Salmon admits the solution of the question by natural selection when he says the 'recovery is due to the ability of the cells to resist the poison.' Immunity is also due to the same fact. The oxygen theory is, therefore, only a rider to the true solution—very much such a rider, too, as Mazeppa was, in so far as ability to guide the horse is concerned." If Dr. Curtiss will consent to lay aside his dogmatic assertions for a moment and consider the, to him, apparently dry and uninteresting facts of the problem, I may once more be able to show how far astray even a philosopher may be led by trusting to a too superficial glance of a subject. Take the disease known as fowl cholera for example. The germs of this disease multiply so rapidly outside of the body that gallons of any nutritious liquid in which a few are placed would be swarming with them within thirty-six hours. Still, inoculate a susceptible chicken weighing not over a pound, and it will be four to six days before the first signs of the disease appear. In other words, although the germs have found their way into the nutritive liquids of a susceptible organism, their multiplication has been checked in a remarkable manner by the influence of the body protoplasm. If a sufficiently small quantity of the virus is used for the inoculation, the microbes are unable to multiply in the body at large even after the period of incubation has passed, but their multiplication is confined to the locality in which they are introduced. Again, if the number of microbes introduced into the tissues is sufficiently small, say twenty-five or fifty, there is apparently no multiplication at all; the bird does not contract the disease, nor are there any signs of local irritation, although the cells have never before been subjected to the influence of the poison, and consequently have not acquired in that way any ability to resist it. Take one more fact; the germs of a contagious disease are unable to multiply in the liquids of an animal that has acquired insusceptibility, although they are placed directly within the blood or lymph channels.

These phenomena are all of the same nature, and they demonstrate, each in its way, the same fact—viz., that the protoplasm of the living body has a means of combating microbes which is not physical, and that it exerts this influence over the fluid which surrounds it to a considerable distance beyond the layer that is in actual contact with it.

These facts are evidently very intimately connected with the question of immunity, and any theory which attempts to explain immunity must not only show how the cells acquire the power to endure and recover from the effects of the poison excreted by the microbes, but it must also explain why the multiplication of these micro-organisms ceases and becomes impossible even in the liquids of the body and where they are not in actual contact with the cells. The tissues are, as we know, penetrated by channels some of which contain blood and others lymph, and there are everywhere spaces between the cells filled with a nutritive liquid which sustains the life of these minute constituents of the body. These channels and spaces, compared with the size of the microbes, are simply enormous, and, without the part of my theory relating to the oxygen supply, we can no more understand how the cells (in their walls) can prevent the multiplication of the microbes in the liquids flowing between them than we can conceive of the

trees on a river's bank preventing the multiplication of the fish in its waters. There are only two conceivable explanations of the phenomenon; one is, that the cells excrete something injurious to the microbes, and the other is, that the cells withdraw something essential to the microbe's growth. The former is untenable, because the liquids which are unsuitable to the microbe's growth when within the body of the insusceptible animal become very favorable for its growth when removed from the influence of the living protoplasm. Evidently, then, they do not contain any injurious principle. Turning to the other explanation, we must admit for the same reason that whatever is abstracted by the cells must be something that can be supplied by contact with the atmosphere. Now, is there any other element than oxygen which can be supplied by the atmosphere and at the same time is so essential to the multiplication of the microbes?

From the facts I have mentioned, and from many others which I have neither the time nor the space to enumerate, it has seemed to me that when the cells are exercising their functions in a normal manner, they have such an affinity for oxygen that this gas is completely removed from the liquids in the interior of the body; and, consequently, microbes which require oxygen can multiply only when sufficient poison is introduced with them, or when they are present in sufficient number to produce enough poison to depress the activity of the cells and prevent them from so completely taking up the oxygen. This theory may be wrong, but it certainly explains facts which have not been explained in any other way; and, if it is to be overthrown, I presume this will be accomplished by bringing forward some facts with which it can not be reconciled and by developing a different theory which, while it explains the new facts, will not contradict the old ones.

It seems unnecessary for me to answer the charge that my theory is too narrow, for Dr. Curtiss no sooner makes it than he sets himself about whittling down even this narrow theory, and soon asserts that a part of it—the part which assumes the acquired ability of the cells to resist the poison—is all that there is to the whole question of immunity. The inconsistency of this part of his argument is too apparent to need any criticism.

Now a final word as to the utility of the studies of immunity, and I hope I shall be permitted to withdraw from the discussion. I shall not attempt to conceal my astonishment that a professor of hygiene can be found in this country who deliberately writes that "the study of physically acquired immunity from disease is interesting only as a means or end of scientific accomplishment, and is of no great practical value. . . . Why not destroy the microbe before it attacks the man, and gain the immunity by this means? . . . Immunity from disease gained by costly combat with poisonous microbes is the method of nature without intelligence. The method is not worth imitation except provisionally." That is to say, vaccination for the prevention of small-pox, the method of all others which is relied upon in every civilized country to hold this disease in check, "is of no great practical value, and is not worth imitation except provisionally." How is it, I would like to ask, that we still rely upon vaccination to prevent small-pox if it could be so easily combated by destroying the microbe before it attacked the man? Why is it that we at the present day, in the United States, are losing every year 20,000 human lives from scarlet fever, 45,000 from diphtheria, 14,000 from whooping-cough, 11,000 from measles, and 120,000 from tuberculosis, and all of these germ diseases? Is it not because the destruction of the germ before it attacks the man has been found impracticable and, in the present state of society, impossible?

The prevention of small-pox by vaccination has been a grand and wonderful success—it is the one solitary success to which the medical profession can point with pride in its long struggle with the indigenous, contagious diseases. And this we are told is not worth imitation, because it is the blind method of nature. What is there so terrible in gaining immunity through actual disease as is practiced on so large a scale in this same vaccination? And who dare predict at this time that we shall not, in a few years, have the virus of the greater part of the contagious diseases so mitigated that their effects will be as mild as those of vaccine lymph?

There is another possibility even more desirable than this. We have seen that immunity is acquired by the cells becoming accustomed to the action of a certain poison excreted by the disease germ. Suppose, as the result of such studies, the chemist of the future is able to separate this substance from the germs and supply it, as quinine is now supplied, in a condition of purity. And suppose, as is very likely, that the introduction of this substance into the tissues would confer as complete an immunity as occurs when it is produced there by the germs, would this not be a solution of the question worthy of many years' investigation?

Until we succeed better than we have in the past in destroying the germ before it attacks the man, let us not insist upon this method to the exclusion of all others, at least so long as over two hundred thousand of our population annually testify by the sacrifice of their lives to the inefficiency of this method.

DARWINISM AND IMMUNITY.

By R. G. ECCLES, M. D.,
BROOKLYN.

Broad generalizations are excellent. They co-ordinate a host of facts in a general way. To rest satisfied with such a mere outline is essentially unscientific. It is a deplorable fact that many intelligent people use them to juggle with. They seem to imagine that everything is settled when it is found that some magic formula does not disagree with the facts. They may dimly see, but fail to appreciate, the truth that within every general hypothesis many particular ones must be held. Waves of ether can in a general way explain the phenomena of light, but, when diffraction requires explanation, we must supplement it with curvings around a sharp edge and interference. The theory of natural selection has, by the consensus of the competent, been pronounced tenable. We need not on this account dazzle our mental vision with its luster until unable to de-

tect its minute interactions in particular cases. To say that natural selection is an essential factor in the acquisition of immunity from disease is only to utter a truism. Immunity, in its broad sense, is clearly due to the survival of such animals as have acquired some power of resistance against disease. In stating this we explain nothing more than is usually perceived by all medical men. Our entire period of life is only possible because of the accumulated gifts of heredity. The power to adjust every part in a manner favorable to the resistance of antagonistic forces constitutes the totality of physical life. In gaining a new readjustment against disease, our cells do nothing more than all cells appear to have been doing since the very beginning of life upon this planet. Variation has been going on incessantly and in all conceivable directions. The conserving force of heredity, with its strange and occasionally acting form of atavism, has preserved these wonderful powers of immunity we now possess. When, however, we wish to explain particular cases of the subtle interactions of variation and retention, new facts and new hypotheses are involved. The mere fact of immunity is no longer the only thing we require light upon.

In the "New York Medical Journal" for July 11th and 18th Prof. Curtiss advances as his the general theory of selection as applied to immunity. It is a true theory, but very incomplete, and entirely too elastic to suit particular cases. There can be little doubt of its having been entertained by Dr. Salmon before he supplemented it with his own. In fact, they are parts of one another. The most general part being inadequate required the particular addition to explain particular cases. While the general law covered the fact of immunity, it gave no hint as to why one disease was self-limited and another was not. Why do the pathogenic microbes of measles soon die out, while those of tuberculosis remain for many years to multiply, and finally destroy the patient? There must be some reason for the rapid adaptation in one instance and its slow appearance, or perhaps non-adaptation, in the other. To this question the general theory has no reply. The particular one explains it lucidly. Why does one attack of small-pox give greater immunity than ten attacks of intermittent fever? Why does cultivation of pathogenic microbes in limited supplies of free oxygen make them more virulent? Why do harmless bacteria become dangerous disease-breeders when so cultivated? Why does cultivation of anthrax in large supplies of air, as accomplished by Pasteur, render it so mild that it can be used for inoculation, and, when carried far enough, make it harmless? Salmon's theory has a rational explanation of all these and many more facts which the general theory can only ignore. The weakest link in the whole chain of Dr. Salmon's theory is the one commended by Prof. Curtiss. The strongest one he rejects. Every experiment so far tried has utterly failed to verify the assumption that the method of warfare of pathogenic microbes is by poison, and that immunity comes from resistance by the cells to this poison. If this point could be established the hypothesis would be demonstrated. It can only be verified by experiments upon the cells. Prof. Curtiss tells us that this is the only truth in Salmon's theory. Dr. Salmon would certainly be rejoiced if Prof. Curtiss would give him the proof of its truth. He has waited and worked nobly for years trying to get this proof, but, alas! it does not yet appear. The oxygen part of the theory for which the professor shows so much contempt is based upon the nature of the microbes, so that its substantiation is as perfect as it possibly can be until it is verified as a whole. Aërobic microbes become pathogenic when modified by submersion into amphibious. This is the full extent of modification to which they have been proved susceptible. Prof. Curtiss tells us that *Bacillus subtilis* has been transmuted into *Bacillus anthracis*. He therefore indorses Buchner's idea, which is rejected totally by all bacteriologists. It has been proved that when Buchner was at work trying to accomplish this miracle his room was full of *B. anthracis* spores, and that, his alkaline solutions being their natural medium, they necessarily had a sowing and growth. The *B. subtilis* which he planted, being only capable of development in acid solutions, perished. The common morphological appearance of the two species deceived him. No one has ever been able to do it in a non-infected room. Prof. Curtiss is unfortunate in indorsing unsubstantiated positions.

Given such micro-organisms as can barely live in the quantity of oxygen supplied by our blood, and without some toxic principle by which to damage the cells they would be harmless. Given now a deadening ptomaine to arrest cellular function, and the air-supply will at once increase. Experiment has shown that harmless bacteria become pathogenic when introduced with a heavy physiological dose of atropine. Experiment has also shown that such bacteria perish unless the solutions containing them are well aërated. With such organisms and their poisonous ptomaine, their rapid multiplication will soon overwhelm the cells. We shall have disease. Now given a modification to the cell by virtue of which it can resist the paralyzing action of the ptomaine, function will be re-established, oxygen consumed, and the already half-choked microbes perish rapidly. The life-history of such microbes, under the given conditions, runs exactly parallel with the invasion, incubation, and self-limitation of such diseases as measles, scarlet fever, and small-pox. Such microbes require more air than the cells, since the cells meet their exact adaptation to the work of the skin and lungs. But there is known to be another class of microbes which Pasteur calls anaërobic. They can live on even less free oxygen than cells. These, according to Dr. Salmon, cause an entirely different class of diseases. The general theory championed by Prof. Curtiss can make no such distinction. It explains all alike, and, according to it, there should be no such difference in diseases. In intermittent and remittent fevers, tuberculosis, etc., there is no such self-limitation nor following immunity. Why? In malaria the system is overcome by the poison and the microbes, but fails to gain immunity. Rally as it will, it can not expel its foes. Their power of absorbing oxygen is too great to ever be damaged by the restored function of the cells. Tubercle spreads in spite of any limitation of oxygen. It can steal from cell-tissue if not secured from the blood. The facts of the dis

ease and the facts of microbic nature agree precisely. Dr. Salmon points out this agreement. Immunity to anaërobic microbes can only come after generations of selection, if at all. Immunity to aërobic or amphibious results from personal experience. No other hypothesis tells wherein these broadly contrasted classes differ.

Prof. Curtiss says that, according to Dr. Salmon's theory, "the inhalation of oxygen ought to not only cure, but prevent all diseases of zymotic origin." The professor seems to be as unfortunate in the inferences he makes as in the proofs he cites. The very reverse of what he says must be true. To supply more oxygen is to save the microbes from asphyxiation and add to their ability for ill. How he drew a reverse conclusion from the words he quotes is certainly a mystery. Facts support the true implication as he has pointed out. To say that "it is evident that we can substitute nitrogen or bile in place of oxygen" is to talk nonsense. Do microbes perish for lack of free nitrogen or bile? Does cultivation of them in limited supplies of nitrogen or bile make them more virulent? Is free nitrogen or bile a life necessity for them and cells? Would their excreted poison arrest the absorption by all cells of nitrogen or bile?

The man and dog illustration is anything but apt. Almost every condition is subverted. Had he put man and dog into a diving-bell, with a pump supplying barely enough air for the man, the cases would have been nearer parallel. Let the man now use up all the oxygen from the dog. The gasping animal, by grasping for his trachea, will succeed in securing a supply for itself. As soon, however, as the man frees himself from the dog, the latter must die. With the case so stated, the oxygen theory becomes much more than a Mazeppa rider. If the professor thinks that the surplus of oxygen is as large in the blood for the number of cells it sustains as it would be in a well-ventilated room for only a man and dog, perhaps he will not object to close the ventilation of his body and see whether it will last as long as that of a room containing a man and so closed. The inhibition of cellular function is the inhibition of oxidation. Will the professor kindly inform us if it likewise is the inhibition of nitrification, or of the absorption of bile in the same extensive manner?

Innovations that oppose established custom are usually considered bad affairs. The promulgators are pronounced absurd and illogical. On the whole, this is right. The vast majority of proposed innovations are but the chatterings of cranks. The conservative instincts of men socially represent the biological law of heredity. Innovations are but variations. For every useful variation there are probably millions of useless or even mischievous ones. Conservatism does a good work in challenging all, and only surrendering when the last credential is presented and understood. He who proposes an innovation is unmanly if he dares not defend it when called to the task. It is not pleasant to stand amid an army of semi-lunatics and be classed with them. One's only consolation lies in the fact that extremes are all alike. The ultra-violet rays of the spectrum are as dark to our blind eyes as real darkness. A man with clear ideas beyond his fellows seems the same to them as the fool or lunatic, whose utterances he knows are folly. But even the brightest thinkers have erred, so that it is the part of wisdom to challenge everything new. To assert that inoculation or vaccination after exposure to small-pox is a dangerous proceeding is to fly in the face of established custom and wage war with conservatism. There are two theories now in the field regarding this point. The first asserts that, so far from being dangerous, it will mitigate or altogether prevent an attack. This theory, like the geocentric one in astronomy, has the sanction of age and customary belief. The fathers taught it, and the sons must believe it. Its genesis can be traced to the bastard generalization, *similia similibus curantur*. It offers no other rational explanation for its existence. Its anomalies are as mysterious as the sphynx. The little sound experimental knowledge we possess seems to negative it. Its defenders appear to be as utterly oblivious of what constitutes valid proof as religious zealots in an experience meeting. It offers no scientific proof of any kind. The same custom, to which it is indebted for its very being, forbids our attempting to either prove or disprove it in the only way it can ever be satisfactorily done. By human vivisection we must discover the power of resistance of those we propose to use for proof. By the same we must learn to measure our doses of virus. With a standardized virus and standardized patient we can prove or disprove the point. Without these we are totally at sea. Accidental inhibitions of virus can never give sound premises upon which to reason. If we could measure our doses of small-pox virus and discover just how much a patient could stand without taking the disease, the matter would soon be settled. If, after taking a given quantity of standard virus, a number of persons with a common resistance were divided into two parties, the one vaccinated and the other not, and while the former escaped the latter took the disease, the case would be clear. But where can we find such proof? Instead of it, a lot of ill assorted and little understood personal experiences is cited. Every so-called fact must be supplemented by an assumption fatal to even an approach to accuracy. They must assume that the person had never before been vaccinated. They must assume that he had no extra supply of resistance, and would have taken the disease or been worse with it, but for vaccination. They must assume that he imbibed just enough of the virus to produce certain results. In fact, every important point must be assumed to suit the fancy of the reasoner. What wonder that the conclusions are always just such as are wanted? Even if we had results from large bodies of men like soldiers to reason from, the law of general probabilities would avail but little. Our data would be so very insecure, scarcely anything could be made out. Proof, therefore, from human experience, of the truth of either theory is utterly valueless, and it is but a waste of effort to cite it. Our only available proof must be derived from general principles and from experience among animals with analogous diseases. The second theory is opposed to the one given, and declares that vaccination after exposure to small-pox assures to some of those so exposed and vaccinated an attack of the disease which they would have escaped but for the vaccination. It also asserts

that such as have imbibed a minimum amount of the virus before vaccination will suffer more than by being vaccinated at another time. So far as experimental proof on human beings is concerned, this theory is as baseless as the first. So far as any proof is concerned, they are both merely guesses of great or little probability. Experiments upon domestic animals have, in the hands of several investigators, shown the last theory to be true, at least for animals in their diseases. This proof is the same in kind as that upon which we accept the germ theory of disease. We are not allowed to prove either upon men. Even condemned criminals, who, by their death, might do that good to humanity they failed to do when alive, are wasted upon the gallows. If Salmon's theory of immunity is true, this vaccination theory is likewise true. The latter is implied by the former. Even the more general theory accepted by Prof. Curtiss appears to imply it. There can be no curative power in the virus of either kine-pox or small-pox. To believe otherwise is to believe homœopathy. The latter insures protection to the former, not because they antagonize one another, but for a reverse reason. Meeting the one teaches how to resist the other, because of likeness. They vary only in degree of strength, not in quality or mode. Such is positively known to be the case with all artificially prepared viruses of charbon, chicken cholera, hog cholera, and hydrophobia. Kine-pox is but a weak or sickly form of small-pox, as experiment has shown, and as the history of the former, so far as known, seems to confirm. A short period of incubation, in inoculation, appears, from Pasteur, Salmon, Detmar, and Law's experiments, to be due to its local character. A tenth of a milligramme of microbes or less will not take as long to develop and fill a local sore as ten or more milligrammes to infect the whole body. Vaccination produces a local sore in which the microbes are confined. The ptomaines osmose through into the blood, producing the constitutional symptoms and weakening the vital resistance of the cells. With weakened vital resistance, even according to Prof. Curtiss's natural-selection theory, the microbes should have more favorable conditions for rapid multiplication. The period of incubation is only the period of microbic multiplication by fission. How, then, can immediate vaccination mitigate or destroy a threatened attack of small-pox? Wherein does a shorter period of incubation of the former make it give protection to the latter? Its short period can only shorten the period of the latter and hurry up the attack. They are not bane and antidote, as Prof. Curtiss assumes. They are either identical or synergistic poisons, and in no respect comparable to atropine and morphine. They have no antagonisms. At least, none have ever been proved. They aid each other, not because of antagonisms, but because of identities. The cells learn to antagonize both from one, because of their features of identity. When Prof. Curtiss asserts such antagonisms between them, he gives up his natural-selection theory of immunity. He says: "Their antagonisms may depend upon the priority of their invasion of tissues." We have not one particle of proof that they have any antagonism. He merely assumes such. He forgets, too, when trying to give a reason for this imaginary antagonism, that the small-pox virus enters first and the vaccine virus last. The long period overlaps the short one so that their terminations may coincide, and they fortify one another with all their might. If such antagonism was a fact, the period could not possibly have anything to do with it, as is here seen. It must be radically lodged in the viruses. But how will he explain Pasteur's virus, Salmon's virus, and the many other artificially prepared viruses where we positively know there can be no antagonism? If the viruses are radically antagonistic, we can have no immunity from them by any acquired antagonism of the cells. The tobacco habit gives no immunity in the use of arsenic or strychnine. Either Prof. Curtiss must give up his theory of immunity by natural selection or his theory of antagonism between the viruses of kine-pox and small-pox. They are thoroughly incompatible and mutually destructive. His Socratic and Durham arguments are funny but not to the point. Does he not take a little too much license in using atavism (L. *avus*, a grandfather) as synonymous with heredity (L. *heres*, heir)?

REFLECTIONS ON THE ÆTIOLOGY OF THE SIMPLE INFLAMMATORY AFFECTIONS OF THE UPPER AIR-PASSAGES.

By JOHN N. MACKENZIE, M. D.,
BALTIMORE.

(*Concluded from page 290.*)

Besides being predisposed to or conditioned by pathological states of the system as a whole, *catarrhal affections of the nose and larynx are not infrequently the result of reflected irritation from its individual parts*, as, for example, disease, over-stimulation, or suppression of the functions of the cutaneous (eruptions, suppression of perspiration, etc.), gastro-intestinal (habitual constipation, hæmorrhoids, parasites, etc.), or genito-urinary apparatus (Bright's disease, utero-ovarian irritation, etc.), teeth and gums (caries, dentition, etc.), external auditory meatus or middle ear (inflammation, impacted cerumen, parasites, etc.). Let us examine this subject more closely: As the respiratory passages and skin are the sole avenues through which oxygen reaches the blood, and as they are held in close consent by virtue of their community of function, it naturally follows that the abrogated activity of the one will necessitate vicarious action on the part of the other. This supplementary or compensative action, if prolonged, sooner or later transcends its physiological limits and eventuates in morbid conditions of the organs whose machinery has been thereby overtaxed. Familiar examples of this vicarious action are the congestion or inflammatory disorders of the respiratory apparatus which follow sudden or prolonged interference with the cutaneous functions, as in sudden chilling of the external surfaces or in the exanthemata, the sudden suppression of tinea capitis and eczema, and, on the other hand, the night-sweats of consumption. One word in regard to the eruptive fevers. The catarrhal naso-laryngeal disease may usher in the attack (especially is this the case in measles), may occur coincidently with the exanthem, or may follow the disappearance of the latter, or, finally, it may not develop until convalescence has begun. The catarrhal affections complicating the essential fevers may dis-

appear completely during the latter period, but in many cases go on to the chronic state. This is especially true, in my experience, in regard to affections of the naso-pharyngeal space. *There seems to be a special tendency to the localization of the disease in this region, and a large majority of the cases of hyperplastic conditions of the adenoid tissue coming under my observation, are directly traceable to some acute blood-poisoning in infancy, as scarlet fever, measles, diphtheria, etc.* This is doubtless due, to a great extent, to the fact that the naso-pharyngeal affection is overlooked by the attendant; but it may be that the *tendency of the eruptive fevers to leave traces of their existence in the glandular structures of the throat (notably the tonsils) may determine diseased conditions of the adenoid elements of the nasal pharynx.*

It now and then happens that during convalescence from acute infectious processes *irregular fluctuations in the temperature* occur, and even a veritable septicæmic condition, inexplicable by the ordinary examination of the functions of the patient, and which depend upon the persistence of the inflammatory process in the retro-nasal space. I have observed this after scarlet fever and diphtheria, but there is no reason why it should not occur in other and allied affections. This is an important practical point, for by simply cleansing the naso-pharynx of decomposing secretion (I find bichloride of mercury to be the best agent for this purpose) the temperature becomes normal and the disagreeable symptoms dissipated. In this connection let me observe that in all infectious processes characterized by inflammatory manifestations in the pharynx the greatest relief to the child may be secured through careful cleansing of the retro-nasal cavities. In diphtheria, for example, the greatest comfort is experienced by attention to this expedient. To digress still further: In the ordinary acute catarrhal throat affections of infancy much comfort may be given, and the tendency to spasm diminished, by careful attention to the nasal and retro-nasal cavities.* There is an old woman's saying in this part of the country that "if a croupy child sneezes, it is well." But no one ever thinks of the nasal passages in connection with a croupy infant. Yet there is, nevertheless, always more or less inflammation of the post-nasal passages, and the tendency to spasm may be diminished by cleansing the passages of mucus, especially before the child retires for the night.†

There is an affection of the skin which is observed in connection with certain forms of coryza, and notably that of sympathetic origin, or rhinitis sympathetica. I refer to urticaria. It appears and subsides with the coryza, and seemingly depends upon the imperfectly defined neurosis or vaso-motor influence which is probably the connecting link between the two affections (possibly some functional derangement of the cervical sympathetic).

Passing now to the *reciprocal relationship existing between the turbinated nasal tissue and the auditory meatus and middle ear*, it is not an uncommon matter in my experience to find that the subjects of chronic nasal inflammation suffer from a more or less constant dryness and itching of the former or a tendency to the inspissation of cerumen, and this, apart from existing disease of the middle ear. I have on several occasions adverted to the rôle of congestive conditions of the erectile tissue in the production of middle-ear affections (doubtless through reflex influence). It remains for me to call your attention to the fact that unilateral coryza, either acute or chronic, sometimes depends upon irritation of the external auditory passage. Two years ago I was consulted concerning a case in which a severe unilateral discharge, with stoppage of the nostril, hemicrania, and other phenomena referable to the same side, of a number of weeks' duration, was completely dissipated by the removal of a mass of impacted cerumen from the ear of the affected side; and recently a similar case has come under my professional care in which the swelling of the erectile tissue disappeared upon removal of the ceruminous plug. In the presence of these facts the conclusion is irresistible that an intimate physiological relationship exists between the nasal cavities and the auditory meatus.*

It has thus been shown *that nasal and laryngeal inflammation may proceed from the direct or indirect (reflex) irritation of a host of substances derived from the external world, from an almost indefinite number of pathological conditions of the system as a whole, or from irritation or disease of organs distant from the seat of local inflammation.* The predisposing influence of *certain structural peculiarities of the nasal chambers* remains to be briefly adverted to. These consist most commonly in deflection (or malposition) and perforation of the septum, anomalous conditions of the turbinated bones (hypertrophy, abnormal position, atrophy?), and disturbance of the anatomical relations of the nasal fossæ either through accident or disease. There are certain anomalies of structure of the throat and nasal passages that are seen in several members of the same family which are undoubtedly inherited and which are of such a nature as to give rise to no inconvenience, or, on the other hand, encourage the development of inflammatory processes; in the latter cases their influence is purely mechanical. There also exists in some families a *peculiar vulnerability of the mucous membrane* of the nose and throat which is sometimes conspicuous for several generations. Such persons are said to "inherit" catarrhal inflammation or to be the subjects of the "catarrhal diathesis"—a view which has descended to us chiefly from the earlier French physicians. It is un-

* In this disease, too, the paralytic condition of the palatal muscles interferes materially with the voluntary removal of secretion from the retro-nasal space.

† *The influence of the febrile state is also occasionally exerted in the direction of cure of existing catarrhal disease of the nasal passages and throat.* This is especially true of those affections with special tendency to local manifestation in the throat, and the cure may be permanent or temporary. I have also observed complete disappearance of a naso-pharyngeal catarrh during the course of malarial fever. (See paper read before this association at its last session.)

* In certain persons, notably those of highly developed nervous organization, or in the hysterical or hypochondriacal, coryza is occasionally produced by direct impression upon the olfactory nerve, or, from simple association of ideas, by physical or mental over-exertion or emotional excitement. Here there is usually some co-existing local nasal disease or vaso-motor neurosis, and such cases are closely allied to, if not a part and parcel of, the sympathetic form of rhinitis (rhinitis sympathetica). (See abstract, in "Maryland Medical Journal," April 11, 1885, of paper read before the Clinical Society.)

doubtedly true that the children of parents debilitated by disease, excesses, or other causes, or who inherit, for example, the enfeebled constitution of the syphilitic or tubercular, diatheses well known as predisponents to catarrh, may, by virtue of the inheritance of a vice of constitution, yield more easily than those of healthy parentage when exposed to the exciting causes of the disease; but there is no evidence yet adduced that puts beyond a reasonable doubt the descent of a simple inflammation from father to son. These remarks apply with equal force to the so-called catarrhal diathesis, which latter may be looked upon simply as a generic term for a multitude of varied physical peculiarities, each susceptible, upon close analysis, of reference to a definite and tangible cause, or to a combination of injurious influences.

*Catarrhal inflammations of the nose and throat in the newly born, when not due to gonorrhœal inoculation, probably owe their origin to causes operating during intra-uterine life.** It occasionally happens that inflammatory affections of these cavities are *ushered in at some physiological epoch, as puberty, or existing disease dissipated by the nutritive changes which occur at that period.* The subacute laryngitis which occurs at puberty occasionally develops into a chronic inflammation, especially in the subjects of inherited constitutional vices—a fact which it is well to bear in mind both in a prophylactic and prognostic point of view. Inflammatory conditions of the throat and nasal passages occasionally make their appearance at the menstrual period, appearing either coincidently with the uterine hæmorrhage or as the vicarious representative of that process, and I have seen one case where a catarrhal affection of these passages ushered in the menopause and subsided with the termination of menstrual life.†

Ætiology of Pharyngeal and Laryngeal Inflammation.—The chief predisposing causes of acute pharyngo-laryngeal inflammation are the existence of chronic hyperæmia or inflammation of the naso-bronchial tract, abnormal state of vitality from inherited or acquired disease, excesses, subjection to imperfect sanitary conditions, and constant confinement to a vitiated atmosphere. While in the vast majority of instances acute inflammation of the pharynx or larynx occurs as a complication of acute or chronic naso-pharyngeal (or bronchial) catarrh, it may nevertheless be met with as a primary affection. I do not share the extreme view of my friend Dr. Bosworth, who has written so well upon this subject, that acute laryngitis only occurs as a symptom of the chronic form. While I regard the existence of the latter as its most prominent predisposing cause, it is nevertheless true that the disease may appear as a primary affection limited to the laryngeal or pharyngeal structures.

Apart, then, from the inflammation resulting from local pathological processes, mechanical or chemical injury, abuse of the forces of expiration and inspiration, the isolation of this disease in the larynx (acute primary laryngitis) is one of the rarest of pathological events. In adult and infant it most commonly occurs as a complication of acute nasal catarrh or as a part of a general inflammatory condition of the naso-bronchial tract. I am inclined to believe that in the irritable state of the nasal tissues, and notably the cavernous bodies, resides an important ætiological factor in the adductor spasm which characterizes the disease in the infant; the engorgement of the sensitive area when the recumbent posture is assumed, and the gravitation of the nasal secretions into the laryngeal vestibule, being the most important agents in awakening the reflex laryngeal spasm. In the adult, acute catarrh of the larynx is a relatively rare disease, a fact which is remarkable, as Flint* has pointed out, in view of the frequency of acute pharyngeal inflammation, and illustrates the conservatism of the natural law in regard to the extension of inflammation.

The reflex or collateral hyperæmia of the larynx which is present in inflammatory conditions of the nasal and pharyngeal cavities is too often mistaken for acute inflammation, and confusion too often arises, especially when the laryngoscope is not available, from failure to remember the simple truth that hoarseness is not laryngitis.

Chronic catarrhal laryngitis as an isolated affection is rarely met with; it is almost invariably secondary and associated with inflammatory disease of the nose or nasal pharynx, upon which it, in the large majority of cases, depends. Indeed, setting aside the inflammation which results from purely local irritation, it may be laid down as a law that the vast majority of cases of catarrhal, pharyngea , and laryngeal disease originate primarily in inflammation of the nasal cavities. Catarrhal rhinitis leads to inflammation of the pharynx and larynx in one or all of the following ways:

1. By mouth breathing, which I may say acts not only through the irritation of the cold, dry, and impure air inspired through the mouth, as in nasal obstruction, or through the nasal passages, as in atrophy of the turbinated structures, but also by crippling the respiratory and vocal forces, shortening both inspiration and expiration, compelling rapid respiration and resulting vocal and respiratory fatigue.

2. By the constant endeavor to overcome the loss of nasal power and resonance, and the consequent pharyngeal and laryngeal fatigue.

3. In certain cases, by interference with the normal motility of the palatal structures.

4. Through reflected irritation.

5. By the irritation of the atmosphere, vitiated in some instances, not by virtue of its passage through the mouth, *but through the nasal chambers themselves.*

6. By so-called extension of inflammation.

7. Possibly by irritation of secretion.

In studying the pathological conditions of the naso-pharyngeal space and middle ear, we may, for practical purposes, regard these cavities as accessory to the nasal chambers, so intimately interwoven is their pathology with a diseased condition of the nasal fossæ. As stated else-

* See article by the author in "Phila. Medical News," October 4, 1884.

† See on this subject a paper by the author on "Irritation of the Sexual Apparatus as an Ætiological Factor in the Production of Nasal Disease," "Am. Jour. of the Med. Sci.," April, 1884. (Prize essay, Maryland Academy of Medicine.)

* "Principles and Practice of Medicine," Philadelphia, 1873, p. 263.

where,* in a large proportion of cases of so-called middle-ear inflammation the latter "is merely a symptom of nasal catarrh, and gradually disappears without special treatment upon the removal of its primary cause." When the middle-ear affection is thus symptomatic, it is generally traceable to mechanical causes or to reflected irritation.

Inflammatory conditions of the naso-pharyngeal cavities are encouraged and existing disease of these structures perpetuated by paralytic conditions or defective muscular power (*e. g.*, from existing chronic inflammation, enlarged tonsils, defective innervation, etc.), or from abnormal approximations of their walls (from adhesions). As a consequence of the impaired functional exercise of the structures thereby induced, congestive and catarrhal processes develop in the laryngeal cavity, which result from the constant endeavor by abuse of the expiratory forces to overcome the loss of power in the pharynx. Both loss of power and adhesions, which latter act by crippling the muscular action and disturbing normal anatomical relations, tend also to prevent voluntary cleansing of the retro-nasal space, and thus form another factor in the persistence of the chronic inflammatory process.

Finally, I wish to observe that in a large proportion of cases it will be found, upon careful examination, that the existence of the nasal, pharyngeal, or laryngeal affection is not due to any one particular cause, but to a combination of injurious influences—the resultant of a number of internal and external forces.

DISCUSSION.

Dr. J. Solis-Cohen: We gather from the essay the fact, not fully appreciated, that many catarrhal affections are due to climatic and constitutional conditions, and that this indicates a feature in the treatment which is too frequently ignored. Climatic conditions can not be altered, but the susceptible individual can be protected by suitable hygienic and dietetic supervision. The function of digestion and the secretions of the intestines and kidneys must be attended to, the skin be kept in good order, and thus revulsive measures be adopted to withdraw morbid influences from the upper respiratory tract. Too great an attention to local measures without due consideration to constitutional conditions does not fulfill the requirements.

Acute laryngitis, in my experience, occurs frequently in individuals who are not at all suffering with chronic catarrhal disease, and subsides without such a sequel. On the other hand, subacute inflammations occur most frequently, in my experience, in the subjects of chronic disease as exacerbations due to some special exposure.

The spasmodic affections of infants alluded to in the paper as occurring in the subjects of chronic naso-pharyngeal catarrh are similar in origin to the night-cough of infants, being due to trickling of mucus into the larynx. The indication, then, is to place the sleeping infant in a position which will not favor the entrance of secretions into the larynx, and, of course, to treat the catarrhal disease.

Dr. H. A. Jonnson: Naso-pharyngeal catarrh is common around our lakes, and is frequently benefited by a change of climate to the Western plains, up to an altitude of five thousand or six thousand feet. In the high mountains the disease is aggravated. In the treatment of this trouble tonics are usually of great value, and we are tempted to overlook the general conditions in the presence of the local lesion.

Dr. Glasgow: I can not strictly agree with the speaker in the relative importance of atmospheric change and dust in producing catarrhal diseases. Although rapid changes of atmosphere lead to catarrhal disease, I fully believe that dust or atmospheric dirt holds the most important place in their production. We find evidence of this in the fact that people living in atmospheres laden with dust are particularly liable to catarrh. For instance, persons living in my own city—St. Louis—are especially prone to these troubles. Removal into the purer air of the country invariably lessens the difficulty, and it is again aggravated by a return to the city. I believe this is the general experience in all dust-laden cities.

We also see evidence of the importance of dust in the experience of people in the alkali regions of the West, and this without special regard to the elevation. Catarrhal disease is the rule in this section. If previously existing, it is aggravated; if the naso-pharyngeal membrane was previously healthy, a commencing catarrhal inflammation is soon noticed.

Dr. Ingals: I agree with the other speakers as to the necessity for attending to the constitutional condition of the patient, but we must not lose sight of the constitutional manifestations due to the nasal disease. In many cases great impairment of the general health, which may have existed for years, is dependent upon nasal obstruction, and remarkable improvement will immediately succeed removal of the nasal affection.

Dr. Allen: The study of catarrh should be considered in great part as a phase of morphology. The careful study of each separate case is important. It is always well to treat individuals rather than diseases. The identification of the local structural cause of the catarrh is, in the majority of instances, alone possible after unremitting scrutiny.

Dr. Mackenzie: I fully agree with Dr. Allen as to the importance of local treatment; at the same time it should not be forgotten that in many instances the balance between cure and failure may be easily turned by neglect of constitutional measures. Cases occur in which local measures must be carried out before relief can be obtained, while, on the other hand, constitutional measures must be employed in order to secure the maximum of good in treatment. Dr. Glasgow misunderstands the position which I took in regard to dust as a factor in the production of catarrh. My proposition is simply this: That the localization of catarrhal processes in the retro-nasal space or the geographical limits of the disease have little to do with the presence of dust in the atmosphere. While it is true that dust accidentally lodged in the naso-pharynx may give rise to inflammation, I believe that few cases originate in this way, for reasons which I have explained in my paper.

ON THE PROLONGATION OF THE ANÆSTHETIC EFFECTS OF THE HYDROCHLORATE OF COCAINE WHEN SUBCUTANEOUSLY INJECTED.

AN EXPERIMENTAL STUDY.

By J. LEONARD CORNING, M. D.

The uses to which the various preparations of cocaine have been put since Koller first discovered the local anæsthetic properties of the alkaloid are legion. To recapitulate these manifold applications of the drug would be manifestly a work of supererogation. Enough that they are such as would naturally suggest themselves to an imagination of

average capacity familiar with the fundamental experiment of the talented young physician of Vienna. So far as I am aware, there has been no departure in principle involved in the various uses to which this truly remarkable substance has been put. And yet I believe that improvements in this direction are not only desirable, but readily attainable. For instance, it would be a matter of practical moment if, by some device, we could prolong the local anæsthetic effects of the alkaloid when used hypodermically for surgical and other purposes. How can this object be attained? To answer this question we must for a moment consider the manner in which cocaine, when subcutaneously injected, is capable of acting upon the filaments of the sensory nerves.

In the first place, it is reasonable to infer that, after the introduction of cocaine beneath the skin, a certain period of time elapses during which the anæsthetic agent is diffused throughout the surrounding tissue. That the blood-stream in the capillaries renders efficient service in this process of distribution may be accepted as proved, since, when the amount of cocaine injected is considerable, characteristic constitutional symptoms are developed.

Secondly, when the terminal filaments of the sensory nerves which ramify in the saturated tissue are exposed for a sufficient length of time to the influence of the cocaine, changes are set up in the nerve-substance of sufficient magnitude to cause interference with conduction, and we have all the symptoms of local anæsthesia. The more extended and important the nerve-stems affected, the wider will be, of necessity, the expanse of the anæsthetic zone.

But, if this is the true logic of local anæsthesia, if we are to look upon the capillary blood-stream as the means by which the anæsthetic substance is distributed, how does it happen that the effects of cocaine, when subcutaneously injected, are evanescent, except where large doses, frequently repeated, are employed? To this question I would reply that we are to look upon the capillary circulation in a two-fold manner: first as a distributor, it is true, but afterward as a *diluter* and *remover* of the anæsthetic substance. The rapid decline in the local anæsthetic effects of the hydrochlorate of cocaine, then, is, according to this theory, owing to the subsequent diluting or *removing* attributes of the blood-stream. The constitutional symptoms developed when cocaine has been extensively injected for local anæsthetic purposes constitute evidence in favor of this view.

Is it possible to adduce inductive evidence in favor of this *a priori* reasoning? I believe so; but not only do I believe that such evidence may be had for the seeking, but I feel assured that the data thus gained may be turned to practical account in the exigencies arising in practice.

Guided by a train of reflections in keeping with those detailed above, I have had recourse to a series of experiments which I will first summarize as briefly as possible, and then offer a word or two of comment, trusting that by so doing I may not incur the criticism of being too prolix.

Experiment I.—This and the following were performed upon Mr. A. M. Guerin, who kindly placed himself at my disposal.

I injected five minims of a four-per-cent. solution of the hydrochlorate of cocaine in the neighborhood of the external cutaneous nerve of the forearm, a short distance below and to the right of the biceps tendon. In a short time the effects of the agent became apparent. The skin for some distance around, and particularly below the puncture, was anæsthetic. After the lapse of a few minutes, judging that the anæsthesia had reached its maximum extent and intensity, I applied an Esmarch's tourniquet around the arm a short distance above the elbow. On examining the radial artery, I found that the pulse was entirely obliterated.

From time to time I examined the condition of sensibility in the forearm, and particularly about the region of the puncture. After the lapse of fifteen minutes the anæsthesia had extended, contrary to my expectations, down the right anterior aspect of the forearm several inches, and was of sufficient intensity to admit of pinching and pricking *ad libitum*. One of the amusements of the gentleman experimented upon, at this and subsequent stages of the investigation, was to thrust needles into the anæsthetic portions of the skin, which was all the more remarkable in him inasmuch as he is a person of rather susceptible and nervous temperament. When I attempted to do the like on other portions of the integument, energetic reflex contractions were evoked, and lively sensations of pain. After the tourniquet had remained in place for over half an hour the anæsthesia was decidedly more profound than during the first twelve or fifteen minutes of the experiment, this profundity of insensibility being without doubt attributable to the long saturation of the nervous filaments in the anæsthetic. Such saturation was evidently only rendered possible by the use of the tourniquet, which, arresting the circulation, prevented the elimination and dissipation of the anæsthetic by the blood. After the lapse of nearly forty minutes I removed the tourniquet, not, however, because the anæsthesia showed the slightest diminution, for the latter, on investigation, proved to be as profound as ever, but on account of the unnecessary tightness of the tourniquet, which caused the gentleman experimented upon considerable inconvenience. In a few minutes after the access of the blood to the forearm the anæsthesia began to decline, and was soon entirely lost.

Experiment II.—I exsanguinated the left forearm by means of the elastic bandage of Esmarch. I then applied the tourniquet above the condyles as before. Ten minims of a four-per-cent. solution of cocaine were then injected at short intervals, the injections forming a line which extended from the radial to the ulnar side of the upper portion of the arm. After the lapse of ten minutes I noticed that the inflated, blister-like elevations which marked the points of injection were quite prominent, and showed no tendency to diminish. I also ascertained, by examinations with a needle from time to time, that the zone of anæsthesia was exceedingly circumscribed, being mostly restricted to the immediate neighborhood of the elevations at the points of injection. Five minutes later, as there was no appreciable diminution in the size of the elevations, and as there was no sign pointing to the slightest diffusion of the anæsthetic, I massaged the parts immediately above the line of injections, and, having thus succeeded in causing some diffusion of the cocaine, I was not surprised to find

that shortly afterward the zone of anæsthesia had increased in width and extended in a band about an inch and a half broad across the entire breadth of the forearm. Into this region needles could be thrust without causing the slightest pain or reflex action of any kind. The extension of the anæsthesia along the districts supplied by the cutaneous nerves of the forearm was, however, not sufficiently pronounced to merit notice. This was perhaps owing to the extremely superficial nature of the injections.

The tourniquet remained in place for over forty minutes, during which time the zone above described was quite insensible to the prick of a sharp needle.

Experiment III.—I first injected five minims in the neighborhood of the external cutaneous nerve of the forearm, as in the first experiment. Five or six minutes afterward, however, instead of applying the tourniquet immediately, as in the first experiment, I first exsanguinated the forearm by means of Esmarch's bandage, taking care *not to compress the tissue immediately above the point of injection.* I then applied the tourniquet. The anæsthetic zone in this case was proportionately much larger than in the previous experiment, following the general direction of the external cutaneous nerve, so far as I was able to judge, in a downward direction, for some three inches or more. The maximum breadth of the anæsthetic zone was perhaps a little less than an inch.

The tourniquet was allowed to remain in place for about an hour, during which time I was unable to note the slightest diminution in the anæsthesia.

Summary.—Experiment I goes to show that simple arrest of the circulation in the part, shortly after injection of the anæsthetic, is sufficient to prolong and intensify the anæsthesia.

Experiment II shows that, if the injection is made *after* exsanguination and compression, there is little diffusion of the anæsthetic, and, consequently, a commensurate diminution in the number of nerve-filaments exposed to the influence of the solution. It is true, however, as we have seen, that by the aid of massage some purely mechanical diffusion may be produced.

Experiment III seems to prove that, if the injection is made a few moments before exsanguination and the application of the tourniquet, a sufficient amount of saturation of the tissue is obtained to expose a large number of nerve-filaments to the influence of the anæsthetic; and yet, unless we wait too long, there is no danger of diluting or dissipating the solution (by the access of too much blood) to such a degree as to weaken or nullify the anæsthetic influence.

The essential advantages of this method of local anæsthetization consist in our ability to expose the nerve-filaments for any length of time to the influence of the anæsthetic. We are thus practically able to prolong the anæsthesia to an indefinite degree. We are furthermore enabled to do this by the use of comparatively small quantities of cocaine, repeated injections being unnecessary to prolong the anæsthesia, as is necessary when the circulation is not arrested. There is, consequently, no danger of constitutional disturbances from overdosing.

It is clear that this method may be applied in the surgery of all the extremities; and in the treatment of neuralgias and other disorders of the peripheral nervous system it is, I believe, destined to render good service.

CONGENITAL ANKYLOSIS OF THE RADIO-ULNAR ARTICULATIONS.

By B. FARQUHAR CURTIS, M. D.

Omitting the cases of congenital dislocation of the radius and those of entire or partial absence of the bones of the forearm, we find congenital radio-ulnar ankylosis to be a not very common deformity, even if we include those cases in which there is also an ankylosis of the elbow or wrist joint proper. For this reason I think the following case worthy to be placed on record. For the opportunity to report it I am indebted to Dr. William T. Bull, of this city.

Alexander McG., three years old, is the fourth child of healthy parents. The other children are all well formed and healthy, and so is this boy with the exception of a malformation of the forearms. He has had one severe accident, causing the fracture of his right clavicle, six months ago, but the recovery has been perfect. Several months ago his parents noticed for the first time that he did not have the full use of his arms.

Examination.—The arms, forearms, and hands of both sides are of normal strength and of normal outward appearance, the forearms being in a position of semi-pronation. The hands and wrists are normal in form and motion. In both elbow-joints flexion and extension are complete, and the bony points are in their normal relations. But both forearms are firmly fixed in a position midway between pronation and supination. Examination under ether gave in addition only the negative information that the ankylosis remained as complete as before, and that no malformation could be detected in the shape of the bones. It was impossible to discover any abnormal deposit of bone in the interosseous ligament or elsewhere, nor could it be decided whether the obstruction to motion was in the superior or in the inferior articulation, or in both.

The bilateral occurrence of the deformity, and the absence of a history and of any marks of injury or of disease, point to a congenital malformation. The rigidity of the ankylosis indicates a synostosis of the radius and ulna, and, although it is impossible to say at what point this synostosis has taken place, cases already on record make it probable that it is situated at the superior end of the bones.

As to treatment, it does not seem wise to attempt any. The forearms are ankylosed in the most favorable position, so that the only object of treatment would be to gain the rotary motion of the forearm. Robert* maintains that in cases of congenital synostosis the muscles which produce the motions rendered impossible by that synostosis are undeveloped, and consequently an operation is never justifiable; but dissections in such cases have indicated that the failure of development in the muscles is not always so complete as he appears to believe. Still, it is very doubtful whether any improvement could be made or not, and at this early age an operation would be not unlikely to cause failure of growth in the bones by interference with the

* "Des vices congénitaux de conformation des articulations." Thèse de concours, Paris, 1851, p. 219.

epiphyses. Probably time will develop a compensatory action of the other joints, particularly of the shoulder, which will make operative measures unnecessary.

A careful search through the available literature shows such a rarity of similar cases that a short account of them may be of interest.

A. Mitscherlich (Langenbeck's "Arch. f. klin. Chir.," Bd. vi, p. 218) reports the following unique case:

A poorly developed girl, six years old, of healthy family, had been relieved of double congenital club-foot by operation. Both elbows were found partially ankylosed, flexion of the right being possible only to 70°, and of the left to 100°. Extension was normal. Both forearms were in almost complete supination, only a slight degree of pronation being possible. The left elbow was resected; the child died of pyæmia. Anatomical examination showed that in both joints the head of the radius was fixed in front of the external half of the coronoid process of the ulna, where it had been felt during life as a protuberance in the bend of the elbow.* The lesser sigmoid cavity of the ulna was absent. The trochlear surface of the humerus was encroached upon by a circular articular facet for the head of the radius. A projecting crest divided the two articular surfaces, and it was the contact of the coronoid process of the ulna with this crest which limited flexion of the elbow, the head of the radius not coming against the shaft of the humerus. The head of the radius was fixed in its abnormal position by a strong ligament, which, arising from the external condyle of the humerus and the coronoid process of the ulna, surrounded the neck of the radius like the normal annular ligament. The anterior ligament of the elbow-joint was also attached to the head of the radius.

M. Josso ("Bull. de la soc. anat. de Nantes," 12 Nov., 1879) reports on the deformed forearm of a dissecting-room subject whose antecedents were unknown. The superior ends of the radius and ulna were fused together into a single bony mass, the remainder of the bones being in extreme pronation, so that the posterior surface of the radius presented anteriorly. The ulno-humeral articulation was normal, but the external condyle of the humerus was absent, as was also the head of the radius. On the anterior surface of the common bony mass was a protuberance which represented the bicipital tuberosity.

Dubois ("Bull. de la soc. anat. de Paris," 1852, xxvii, p. 67) reports a specimen of an old (congenital?) dislocation of the radius and ulna, the radius being elongated superiorly and fused with the ulna from the superior limi of the interosseous space upward. The bones were in extreme pronation.

Dr. v. Becker (Schmidt's "Jahrb.," Bd. 179, p. 13) showed to the Vienna section of the "Ver. der Aertzte Nied. Oest." a boy of a family among the members of which many malformations were present. He had both upper extremities deformed, the left forearm and elbow being absent, while on the right side the humerus was too short, and the radius and ulna were fused into one bone one third of the normal length.

T. Jones ("Brit. Med. Jour.," 1878, i, p. 709), in describing a case of multiple exostoses in a boy of nine years, mentions that the patient also had a deformity of the left forearm, the lower part of the ulna being quite rudimentary and united to the radius, movements of rotation being impossible, but he does not describe the position of the forearm.

Girandeau ("Bull. de la soc. anat. de Paris," 1881, lvi, p. 271) reports a malformation of the left forearm in a woman twenty-six years old, the arm being small, the elbow ankylosed, the forearm in extreme pronation, the hand deformed, the carpal bones fused together and to the radius and ulna, and the metacarpal and phalangeal bones absent.

Pye-Smith ("Med. Press and Circ.," Lond., 1883, Dec., p. 504) describes a family having various deformities. Among others, we find that in the father the right hand can not be fully supinated; one son has the same defect in both forearms; in a daughter neither elbow can be fully extended; and in two other children there exists a congenital dislocation of the radius in one elbow.

J. H. Pooley ("Illustr. Med. and Surg.," July, 1883, p. 163) describes a girl, ten years old, with absence of the left radius, who had on the right side a very short curved (concave radially) forearm in which all the motions are "circumscribed and imperfect, from what cause, however, does not clearly appear." The right thumb was also absent.

Lenoir presented to the Soc. anat. de Paris ("Bull.," 1827, ii, p. 95) the left forearm of a young girl who had suffered from rhachitis, in which the bones were crossed as in pronation and fused together for a considerable space at their upper extremities.

Congenital ankylosis of any joint, excepting those deformities which occur with club-foot and club-hand and in monstrous fœtuses, is so rare a condition that a few more references will exhaust the list of recorded cases which I have been able to find.

In the fœtus at full term ankylosis has been observed by Busch (all the joints in one case,* those of the lower extremities in another†), Jänecke (one case,‡ both elbows and right shoulder), Hohl (several cases #), and Bécourt (one case, ‖ one knee) △.

In the adult and child we find only the following additional cases:

Gurlt gives a case of congenital synostosis of the second and third cervical vertebræ, and several cases of synostosis of the pelvic bones in deformed pelves.

Bordet ("Bull. de la soc. anat. de Paris," 1836, xi, p. 82) reports a case of fusion of the radius and humerus, with partial absence of the ulna, in a man of twenty-seven years.

In the same society's records ("Bull.," 1854, xxix, p. 72) is described a specimen of bones showing fusion of the humerus and ulna, the radius preserving "free movement"; the history of the subject from whom it was taken is unknown.

Finally, Velpeau saw a case‡ in which the medullary structure of the humerus was continuous with that of the radius and ulna, with no trace of a joint.

Volkmann‡ teaches that, while congenital synostosis of the bones of the hand and foot may occur in well-developed

* This is the early fœtal position of the head of the radius, from which it passes outward and backward with the growth of the parts to the position in the fully developed joint. subjects, when it is in the larger joints the whole extremity is rudimentary. The truth of this statement is shown by the fact that I have been able to find only the few exceptions mentioned above. I would also draw attention to the fact that the great majority of these cases concern the upper extremity, and to the frequency of pronation of the forearm in them.

A CASE OF DISEASE OF THE SUPRA-RENAL CAPSULES.*

By EDWIN W. MOORE, M. D.,
FRANKLIN, PA.

Dr. Thomas Addison in 1855, by autopsical and general evidences and by crucial analysis, associated a geometrically increasing anæmia, with or without pigmentary deposit, with a diseased condition of the supra-renal capsules. He furnished the profession with the pathological conditions which lead up to and make the pernicious anæmia a possibility; he also associated the general history that this condition is found in subjects beyond the middle period of life and with a predisposition to the deposit of fat. As far as my reading goes, there is but one exceptional authority—*vide* article by Samuel Wilkes, page 562, Reynolds's "System of Medicine," published in 1880. This gentleman takes the position that the disease is of more frequent occurrence before the middle period of life.

My case falls under this exceptional authority, for the subject was of slender build, twenty-two years of age, six feet high, and weighed about one hundred and forty-five pounds. He was of good family history, free from inherited disease, and of good habits of life.

For a period of two years, and possibly more, he suffered a physical depression unaccountable to himself, his family, or his physician; but the inroads were gradual, and sapped his energy until he was compelled to take his bed.

My attention was first called to C. G. C. in October, 1884. At this time I found my patient yellow, with a disposition to bronzing, with a pearly sclerotic, with a weak, compressible pulse, with nausea and vomiting, with furred tongue and red margins, with pain referable to the stomach, with a history of constipation, and, after a meal of indigestible matter, with a degree of depression incompatible with general evidences. At this time I ordered castor-oil and turpentine to unload the primæ viæ, gave a hypodermic injection of morphine and atropine to control the inordinate nervousness, and suggested hot fomentations, sinapisms, etc.

This appeared sufficient, and with a tonic regimen he rallied, got up, and went to his usual work. I suggested a further general treatment, but it was not followed out.

My attention was again called to him May 1, 1885. At this time the general evidences were increased pigmentary deposit; skin of face and hands as dark as any mulatto; nausea; vomiting; furred tongue; constipation; pearly white sclerotic; great feebleness and loss of vitality; restlessness; weak and easily compressible pulse, rate 85; pain over region of capsules; no chill; no fever. I directed small doses of mild chloride of mercury, guarded by morphine, to be followed by a saline; adjuvants, foot-bath, sinapisms, perfect rest, and artificial heat to extremities.

May 2d.—Bowels and kidneys acted, but did not see excreta, because patient went to bath-room; pulse 86, temperature 97°; vomiting less, and yet persistent nausea; restlessness decreased. Directed quinine, bismuth, and morphine.

3d.—Quite comfortable; less nausea; tongue furred in center and red at margins; pulse 90, feeble. Directed small doses of calomel, pepsin, and morphine. Have directed foods and alcoholic stimulants from the beginning, but have found a perfect abhorrence for anything of the kind.

4th.—Tongue cleaner, moist; pulse feeble, better sustained, rate 90. Treatment continued.

5th.—Tongue fairly clean, moist; pulse feeble, rate 84; bowel action *nil;* nausea less; urine fair in quantity and quality. Directed carbonate of ammonium and quinine, with continued frictions, baths, etc.

6th.—Pulse better sustained, rate 86; retains nourishment fairly well; urinary excretion one pint and a half in the past twenty-four hours; specific gravity 1·022, acid in reaction, dark red in color; no sediment. Continued treatment with addition of Apollinaris water.

7th.—Pulse more feeble, rate 84; very sick at stomach during night; vomited largely; excreta green, flaky, with mucus. Directed rectal injection to unload lower bowel; unsatisfactory; little fæcal discharge. Added tincture of iron to treatment. His grand-uncle, Dr. Byles, in consultation at 4 P. M. Result, gave saline cathartic. At 9 P. M. had a thorough dejection; discharge dark brown, with some scybala.

8th.—Pulse 86, feeble; skin moist; kidneys acted freely; no bowel action; tongue moist and clean; nauseated during the night, and very restless. Dr. Byles, who was in the house, gave Dover's power to allay the restlessness and with a hope that the ipecac might allay the nausea. Passed a very restless night.

9th.—More comfortable than in past twenty-four hours; bowels moved three times; stools bilious; rest fairly quiet. Treatment continued.

10th.—Pulse more feeble, rate 96. Directed morphine.

11th.—Condition unchanged.

12th.—Resting fairly; thinks he has had a good day. Treatment continued.

13th.—Quiet; slept peacefully six hours; less nausea; urine normal; pulse 86, temperature 98°.

14th.—Nauseated all day; pulse feeble, rate 90; urine normal in quantity, amber in color; singultus. Added asafœtida to treatment.

15th.—Comfortable; facies indicates extreme exhaustion; circulation very feeble, rate 90; bowels moved three times; excreta green, flakish, offensive; urine normal; tongue moist. Directed quinine, iron, and nux vomica, with friction, and sponging with whisky, etc.

16th.—Passed restless night; less nausea; skin dry; kidney action fair; urine amber; pulse feeble, rate 90, difficult to get at the wrist; temperature normal; foods and stimulants abhorred. Dr. Byles in consultation. On account of extreme restlessness, gave hydrate of chloral.

17th.—Pulse very feeble, and at times imperceptible; tongue furred in body and red at margin; no bowel action; skin dry and harsh; urine abundant; fed by force. Directed digitalis and arsenic, and suggested rectal injections of brandy, milk, and beef-tea, but the patient took the same by mouth in preference. Were retained.

18th.—No bowel action; pulse 90, with better force but easily compressible; very restless. Mother gave hydrate of

* Read before the Venango County, Pa., Medical Society, July 21, 1885.

chloral to allay restlessness. Patient pleasantly affected, but, when asleep, the eyes were turned up, the lower jaw dropped; is nervous and jerking; haggard. Takes food and stimulants by mouth, but with great reluctance.

19th.—Stupid; when aroused, rational; urine scanty; no bowel action; yawning, sighing, singultus; pulse feeble; nausea; restless. Directed carbonate of ammonium, niter, and carbolic acid to allay nausea.

20th.—8.30 A. M.—Passed restless night; pulse rate 90; respirations hurried, lips red as usual, extremities colder, skin dry and harsh; vomited largely; excreta bilious in character. 8 P. M.—Called hurriedly; found patient pulseless, haggard, restless, etc. Gave carbonate of ammonium, brandy, and beef-tea *per rectum*. Continued to sink; heart failure great; anxiety and restlessness indescribable; remained conscious until 12.30 A. M.

21st.—Gradually became quiet, comatose, and died at 1.20, May 21, 1885.

A *résumé* of this history is epitomized thus: Discoloration, exhaustion, pain referable to the capsular region, pearly sclerotic, nausea and vomiting, restlessness and anxiety.

The discoloration through its gradations was sallow, bronzed, smoky black, the last being the tint when last under observation. The discoloration was general, but was most marked on the parts exposed to the air. The exhaustion was very great, the nausea and vomiting were persistent, and the restlessness and anxiety in harmony with the heart failure.

The important feature which attracts attention is the progressive anæmia. And it may be said that this is largely unaccounted for.

The conditions from which it must be differentiated are pityriasis nigra, silver poisoning, Bright's disease, septic poisons in general, and icterus.

The diagnostic points of the four first are known and readily ascertained, but from icterus there is more difficulty to disassociate. I will tabulate the stronger evidences:

Icterus.	Addison's Disease.
1. Slow pulse.	1. Normal to excited pulse.
2. Color sallow.	2. Color anæmic primarily, secondarily sallow, bronzed, smoky black.
3. Sclerotic yellow.	3. Sclerotic pearly.
4. Nausea and vomiting.	4. Persistent nausea and vomiting.
5. Urine impregnated.	5. Urine normal.
6. Bowel action torpid.	6. Bowel action torpid to natural.
7. Appetite fair to good.	7. Appetite seriously impaired.
8. Debility commensurate with poisoning.	8. Debility greater than evidences would indicate.
9. Nervous depression approaching hypochondria.	9. Depression progressive, with a clear mind.

In the general management of my case I found a perfect abhorrence for alcoholic stimulants, for all stimulants, for all foods save such as fountain water and ices.

I made no autopsy, therefore I can not describe the supra-renal capsules, can not add anything to the sum of pathological investigations.

ON A RARE CASE OF CAFFEINE POISONING; RECOVERY.

By EDWARD N. LIELL, M.D.

Cases of poisoning by caffeine are of such rare occurrence that a record of the following case, which came under my observation but a short time ago, I deem may be of interest:

On the morning of July 16th I was hastily summoned to see Miss W., thirty years of age. Found her greatly prostrated and completely exhausted, and in a state of semi-unconsciousness, with cold extremities, clammy perspiration, and anæsthesia and slight paresis of the muscles of the hands and feet. Temperature normal; pulse 55, and somewhat irregular; respirations diminished in number to 16 a minute, slightly irregular. Pupils but slightly contracted, responding readily to light. One thing remarkable was a persistent contraction of the flexor muscles of the fingers and toes, with paresis of the extensors, especially of thumbs and great toes. There was a certain spasmodic action of the muscles of the calves of both legs, which, when conscious, she termed cramp-like pains. She vomited occasionally.

I immediately applied warmth, with revulsive measures to the extremities, and gave atropin. sulph., $\frac{1}{50}$ gr. (tablet triturates), hypodermically; also whisky, ʒj every five minutes, administered cautiously in order to avoid exciting the vomiting. These measures of treatment were continued, repeating the atropin. sulph., $\frac{1}{50}$ gr., hypodermically, as before, in twenty minutes.

A change for the better was apparent almost immediately after the second injection of atropine. She gradually regained consciousness, when she informed me as to the cause of her illness, saying she had taken some eighteen grains of citrate of caffeine inside of one hour and a half during the night. Her mind was still somewhat confused, and she was exceedingly restless and anxious.

She complained of severe paroxysmal pains in the abdomen, simulating very much those of intestinal colic, also of a dimness of vision, with a blur before the eyes. At one time, becoming quite delirious, partly due to the pains in abdomen, she got out of bed and endeavored to walk across the room, but, being unable to stand on her feet, reeled like one intoxicated, complaining of a sudden vertigo with a feeling of numbness in the soles of her feet, and would have fallen but for an attendant close at hand. A certain tremulousness of the fingers of both hands, with tremors of the tongue, was present.

Thirst was excessive, with dryness of the mouth and tongue, relieved by small pieces of ice. There was no headache whatever, except a fullness in the supra-orbital region. Speech was somewhat indistinct, her utterance being at times thick, and there was also some difficulty in deglutition. The heart's action was diminished in rapidity, and its rhythm was irregular. The bowels were constipated. The kidneys were excited to increased action; urination was frequent.

To relieve the intestinal pains, warm turpentine fomentations were applied over the hypogastrium, the nausea and vomiting being relieved by the following: ℞ Sodii bromid., ʒss.; bismuth. subnit., gr. x; acid. hydrocyanic. dil., gtt. j. M. This dose was repeated in fifteen minutes.

About three quarters of an hour after my arrival she complained rather suddenly of a severe cramp in the muscles of the calves of both legs, extending upward, gradually implicating the muscles of the abdomen, chest, and neck, when a sudden and severe convulsive seizure followed, of a marked tetanic character, the abdominal and chest muscles becoming retracted and

rigid; the eyes were suffused, and the facial expression was that of great pain, the respirations being entirely checked and cyanosis very prominent, with the jaws quite rigid, and the fingers firmly contracted. This was followed by a second convulsive seizure of the same character some three minutes later.

℞ Chloral. hydrat., gr. xv, potass. bromid., ʒij, was then given at one dose, and repeated within half an hour. This had the effect of checking the convulsions and rendering the patient quiet. When she recovered sufficiently to collect her thoughts the following *history* was obtained:

After a somewhat immoderate use of stimulants the previous day, and having been up the greater part of the night before she complained of a severe headache and of being very nervous, when a friend advised her to take a two-grain powder of citrate of caffeine; misunderstanding the quantity directed, she had prepared and took a three-grain powder instead. Not getting instant relief, she repeated the dose, and had taken six powders (eighteen grains in all) within one hour and a half, when she began to feel the effects of the combined doses. In the mean time she had sent out for some quarter-grain morphine pills, but had only taken one, being prevented from taking more by a high state of mental excitement. (It may be mentioned here that, according to her statement, she had never been subject to hysteria, but was naturally of a very nervous and excitable temperament.)

During the night she was exceedingly restless and wakeful, tossing about the bed one moment and the next moment walking the floor, the insomnia being persistent, which, combined with her excited condition, bordered on delirium. Respiration was at the time disturbed, her breathing becoming hurried and irregular, with excited and irregular heart action. Reflex excitability was quite marked for a time, when general muscular weakness supervened. In this condition she passed the night, conscious of what was going on and recognizing things about her.

Toward morning the delirium gave way to a condition of stupor or semi-unconsciousness, in which state I found her. After the second dose of chloral and potassium bromide was given her she fell into a quiet slumber, lasting about an hour, when she awoke without manifesting any untoward symptoms or signs of her late trouble, except that a certain stiffness of the muscles, especially of the lower extremities, remained.

From this time on, with rest and quiet in bed, under the treatment described and light stimulating diet, she improved rapidly, the vomiting having entirely ceased, and the ill effects of the caffeine disappeared. The anæsthesia, with paresis of the muscles of the hands and feet, began to gradually diminish, disappearing entirely on the fifth day.

Sodium bromide, in thirty-grain doses every four hours, was kept up for some two days thereafter.

In conclusion, a brief *résumé* of the peculiar effects of caffeine upon the system may not be amiss. They may be divided into *two stages*—that of *excitement or delirium*, and that of *depression or stupor* with unconsciousness.

During the first (*stage of excitement*) the heart action is accelerated; the pulse is increased in frequency; the respirations are more or less rapid and irregular; there are restlessness, persistent insomnia, with confusion of mind, and increased activity of the kidneys. Delirium may or may not be present, the person retaining full consciousness of what is going on and recognizing everything about him. Colicky pains with occasional vomiting are also present. Following on this comes the second (*stage of depression*): the heart action and pulse are diminished in frequency; the respirations are below normal; the pupils are slightly contracted; there are persistent contractions of the flexor muscles of the fingers and toes, with anæsthesia of the same, and paresis of the extensors; there are cramp-like pains, with weakness and stiffness of the muscles of the calves of the legs; there is no cephalalgia, but, later on, stupor or unconsciousness. In this special case almost twelve hours had elapsed from the time of her taking the powders until I was summoned.

As to the controversy in various medical works whether *true convulsions* are ever produced by caffeine in *human beings*, it is a settled fact in my mind that they do occur, as proved in this case.

Correspondence.

LETTER FROM BOSTON.

The Boston Water-Supply.

Boston, *September 14, 1885.*

In my last letter I gave a general outline of the way in which our water-supply is contaminated. I will now go more into detail as to one source. One of the acts of the recently displaced Water Board, and one upon which they prided themselves, was the purification of the various water-basins, but especially that known as "Ashland, No. 4." This is situated in the town bearing its name, and is on a tributary of the Sudbury River known as Cold Spring Brook. This basin is the largest of the Sudbury system. It covers an area of 270 acres, and, when full, will hold 1,100,000,000 gallons of water. It runs through a deep, narrow valley, with high hills rising abruptly on either side. It arises from various springs. The valley consists largely of bogs, and the black mud is very deep in places, with a hard, clean, sandy bottom beneath it, from which hundreds of springs bubble up. During the construction of the basin work was going on in making new parks in Boston, and, as the loam was needed, it was removed and taken to the city. But, as the excavation progressed, it was found that deep pockets of muck or peat existed, extending in some cases over acres and to the depth of seven or eight feet. Beneath them there was a layer of hard, green sand, which was perfectly pure. With the experience of Farm Pond (where the same state of things existed) still fresh in the minds of the people, one would think that the Water Board would have acted in accordance, but, instead of the muck and decaying vegetable matter being hauled out, the surface was simply skimmed, and a thin layer of gravel put over it.

The estimated expense of the work at this basin is a little short of $1,000,000, and yet, after this outlay, the water, which comes from the springs pure and sparkling, is so contaminated that it is not fit for use, and, in order that the money already spent may not be lost, this whole area will have to be dredged till the hard subsoil is reached, after which we may expect the water from the springs to reach us in something like purity. The brook that connects Basin No. 2 with No. 4 not only has its water defiled by the same kind of decomposing material, but also receives the drainage from the houses on its course. This brook also will have to be thoroughly dredged, and the outhouses and other sources of contamination removed, other outlets being provided for the sewage.

Many of our people do not believe that the condition of things is so bad as it is reported, saying that they have no trouble in their houses. If such people will inspect their water-tanks they will soon be convinced. In many instances that I know of, two or three inches of muck and detritus have been found on making such an examination. In places where water is drawn from the street-main direct, without the intervention of a tank, and the water is allowed to settle, the presence of foreign matter is easily detected.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, SEPTEMBER 19, 1885.

THE SURGEON-GENERALSHIP OF THE MARINE-HOSPITAL SERVICE.

In far greater measure than commonly falls to the lot of public officials, even medical officers, has Surgeon-General Hamilton had to contend with envy, hatred, and malice, and all uncharitableness. Thus far he has manfully and successfully striven against these malign influences, while he has not deviated from the decorousness and fairness that should always characterize officers of the Government. At the same time, by his careful, prompt, and unostentatious use of the Congressional epidemic fund, he has shown the utter groundlessness of whatever genuine distrust may at one time have been felt of the committal of such grave and comprehensive responsibilities to a single individual. Add to this the efficient and satisfactory conduct of the Marine-Hospital Service that has marked his incumbency of the chief office of that bureau, and we certainly have the picture of a faithful performance of duties that entitles him to the highest consideration.

And yet there are rumors—but too well founded, we fear—of serious and determined efforts to displace him. There is no pretense, as we understand matters, that any fault is found either with his capabilities or with his official acts, except, indeed, in so far as they may have been distasteful to some *soi-disant* sanitarian; but the honors and the emoluments of his position are coveted as the means of paying off a debt of gratitude to some one of a number of political "workers."

If there were any serious danger of the success of these plots against Dr. Hamilton—and we shall decline until compelled to the contrary to believe that there is—the situation would be grave enough, in these times of civil-service reform, even supposing that his office was one that made him subject to the vicissitudes of the spoils system as heretofore interpreted by politicians. But the post of surgeon-general of the Marine-Hospital Service is one to which Dr. Hamilton rose in quite the same way as a surgeon-general of the army usually arrives at his position, in accordance with considerations partly of seniority and partly of the good of the service. Such appointments are commonly made in complete disregard of partisan motives, and the tenure of office is regarded as secure, in the absence of special cause. Even the machine politicians pass the office over as beyond their grasp.

It is said that a high official of the Government is one of those who have set their covetous eyes on the surgeon-generalship of the Marine-Hospital Service. If this is true, it is reassuring to observe that he is not the only one, for non-interference may prove to have its firmest ground in the antagonisms of rival schemers. Fortunately, however, it is not in

this reflection alone that Dr. Hamilton's undisturbed possession of the office he has adorned finds its chief guarantee; if all indications are to be interpreted in accordance with their plain drift, neither the President nor the Secretary of the Treasury is the sort of man to remove the present surgeon-general with no other motive than to make way for some aspirant whose pretensions may be urged on personal or partisan grounds.

SMALL-POX.

The country has been measurably free from small-pox for a considerable period. Limited outbreaks have occurred here and there at various times, but there have been none of sufficient magnitude to arrest public attention. In particular, the metropolis, where epidemics might naturally be expected to take their start, has, thanks to the vigilance and energy of the boards of health of New York and Brooklyn, been exceptionally free from the disease for a long term of years. Even in the "pandemic" of 1871 to 1873, when Boston, Philadelphia, and Chicago suffered severely, New York was but lightly attacked; and since that time it has been quite the exception for small-pox to figure in our reports of infectious diseases. All this should not lull us into a false feeling of security, however. Thus far—and it is well on toward cold weather—we have escaped the cholera, of which the community has stood somewhat in dread, but for several weeks past there have been warnings which we can not afford to disregard of one of those epidemic waves that have always marked the history of small-pox.

During the greater part of the summer the disease has been rife in Montreal, a city which is in close communication with the United States, and which seems to constitute, so to speak, an ever-active nursery of the infection, in consequence, it appears, of the peculiar obstinacy displayed by a large proportion of its population in opposing vaccination. For a number of weeks, too, it has not been an uncommon occurrence for victims of the disease to effect a lodgment in New York from immigrant ships, especially those coming from Germany. A notable instance of this sort came to light week before last, when a lad was found in a house in Pitt Street who is said to have arrived recently by a German steamship, and to have had small-pox for a week before the nature of his illness was made known. Ordinarily such an event would have little significance, even although, as in this instance, the sufferer was lodged under the same roof that covered a daily assemblage of school-children. Taken, however, in connection with the undiminished and apparently increasing prevalence of variola in Montreal, and its isolated outbreaks in various localities in our own country—at Fall River, for example—it can scarcely be viewed with the equanimity that might otherwise be felt.

Not the least significant of the circumstances that should put us on our guard is the fact that the occurrences alluded to have taken place in summer. It is usually in cold weather by preference that small-pox proves epidemic, but it may not be amiss to recall that the great epidemic of the last decade, which swept the greater part of our country, made its first decided outbreak in Lowell, Massachusetts, during the summer. It would perhaps be going too far to argue from that that an epidemic arising in summer was particularly likely to prove unusually destructive, but it is difficult to avoid the thought.

It is with no desire to play the alarmist that we have thrown out these suggestions, but simply to put our readers on their guard. In the case of small-pox, however, there need be less hesitation in sounding the alarm than with regard to most other pestilential diseases, for popular anxiety may readily be exchanged for security; prevention is within every man's reach.

MINOR PARAGRAPHS.

NEWSPAPER NOTORIETY.

We quite agree with our correspondent who signs himself "Practitioner." On several occasions we have expressed ourselves in regard to the rage for newspaper notoriety which seems to have blinded some of our brethren to the decency and modesty of a truly scientific life. If we have restricted our remarks to those outcroppings of this spirit which have appeared in New York, it is because we have preferred to try to set things right at home before criticising our colleagues elsewhere, and by no means because we have been willing to confess that the offenses referred to have been in any way peculiar to our immediate neighborhood. The metropolis, as being presumably the most advanced in civilization of all places on the continent, should certainly be freest from the foibles of a callow community. If our own sense of propriety did not urge this upon us, we should at least be spurred on to it by the comments which reach us from other parts of the country, and our excellent contemporary the "Medical News," of Philadelphia, has lately made pointed and most amply justified allusion to the breach of taste in question. Moreover, New York is in a certain sense on trial before the country; it is here that the formal restrictions of the code of ethics have in a measure been cast off, and that very fact makes it all the more incumbent on us to show that there are other incentives to a decorous course of life. Our readers will have no difficulty in imagining what the occurrences are to which our correspondent alludes, and we will therefore only add an expression of the hope that no more specific reference to them may be necessary to recall our erring brethren to a proper sense of what is due their own dignity as well as that of our common profession.

THE CURIOSITIES OF LOCAL ANÆSTHESIA.

In this issue of the Journal we publish two communications which set forth remarkable facts connected with the subject of local anæsthesia. We refer to Dr. Corning's article and to Dr. Halsted's brief letter. The explanation given by Dr. Corning of the decided prolongation of the effects of cocaine which he has been able to obtain by annulling the local circulation for the time being is apparently correct and very creditable to his ingenuity. Indeed, it is hardly fair to speak of it as an explanation; it was rather the conception which led to the experiments. If further trial shows that the practice is free from drawbacks which can not now be foreseen, an immense addition will undoubtedly be found to have been made to our resources in local anæsthetization.

Quite as striking and no less interesting, even if its practical utility should prove to be more restricted, is the curious fact set forth by Dr. Halsted, that the intra-cutaneous injection of simple water, properly managed, is capable of giving rise to a temporary and circumscribed anæsthesia. In the light of these two contributions to our knowledge, we may well indulge in the

fond anticipation that general anæsthetization, with all its attendant inconveniences, may soon be found necessary only in exceptional cases.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 15, 1885:

DISEASES.	Week ending Sept. 8.		Week ending Sept. 15.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	36	10	48	9
Scarlet fever	15	1	24	1
Cerebro-spinal meningitis	1	1	5	5
Measles	3	1	1	0
Diphtheria	35	15	38	18
Small-pox	2	0	2	0

The International Medical Congress.—We learn that Dr. R. B. Maury, of Memphis, Tenn., declined the honor of serving as one of the vice-presidents of the Section in Obstetrics and Gynæcology as soon as he received the notice of his appointment.

The New York Post-Graduate Medical School and Hospital.—We have received the first issue of the "Quarterly Bulletin," published by the Clinical Society connected with this institution, and we find it a very creditable production. It contains a well-executed chromo-lithograph showing a syphilitic affection of the lung. The Faculty announce the following courses for the winter of 1885–'86: Diseases of the eye and ear, nineteen hours a week, and a course in the operative surgery of the eye as frequently as classes are formed; diseases of women, obstetrics, and the anatomical basis of gynæcology, sixteen hours a week; general, minor, operative, and orthopædic surgery, nineteen hours; diseases and the anatomy and physiology of the nervous system, twenty-one hours; diseases of the throat and nose, six hours; clinical medicine and therapeutics, urinary analysis, and work in the histological and pathological laboratory, twenty-one hours; venereal diseases, ten hours; diseases of the skin, six hours; diseases of children, twenty-seven hours. Opportunities will be afforded the class to witness autopsies at the Presbyterian Hospital, as well as those that occur in the practice of the instructors in the children's department. The laboratories will be open all day, and every possible means will be employed to facilitate instruction. It will be seen that the institution offers its pupils one hundred and forty-four hours of clinical and practical instruction every week.

A Testimonial to Professor Koch.—The "Medical Times and Gazette," of London, says: "A testimonial has been recently presented to Geh. Med.-Rath Professor Dr. Koch by the practitioners who last winter attended his course of lectures on cholera at the Reichsgesundheitsamt, Berlin. It consisted of an ebony casket richly ornamented in silver, having a silver shield in front bearing the inscription 'Dedicated to Herrn Geh. Med.-Rath Professor Dr. Robert Koch with thankfulness by his first pupils, Berlin, 1884–'85.' A silver plate is let into the lid, on which, in raised work, is a bust of Dr. Koch, on a pedestal, against which the goddess Hygeia leans holding in the one hand the staff entwined by the serpent, the symbol of the medical art, and in the other a laurel crown. A nude child seeks to conceal itself amidst her flowing drapery in fear of a haggard woman at the foot of the pedestal, who with a scythe in her hand symbolizes the devastating disease which Dr. Koch has chosen for the special object of his study. On either side of the pedestal are groups of palms. Prof. Echtermeyer is the author of the design for this relief. The casket is lined inside with dark blue satin plush."

The University of Vienna.—The "Medical Times and Gazette" learns that Prof. Fuchs, of Liège, is likely to be given Prof. Jäger's chair of ophthalmic surgery.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 6 to September 12, 1885:*

McKee, J. C., Major and Surgeon. Sick leave still further extended three months on surgeon's certificate of disability. S. O. 204, A. G. O., September 7, 1885.

Patzki, J. H., Captain and Assistant Surgeon. Assigned to duty as post surgeon, Jackson Barracks, New Orleans, La. S. O. 192, Department of the East, September 8, 1885.

Polhemus, A. S., First Lieutenant and Assistant Surgeon. When relieved at Fort McDermit, Nev., assigned to temporary duty at Presidio of San Francisco, Cal. S. O. 87, C. S., Department of California.

Kendall, William P., First Lieutenant and Assistant Surgeon. Relieved from duty at Presidio of San Francisco, Cal., and assigned to duty as post surgeon at Fort McDermit, Nev., relieving Assistant Surgeon Polhemus. S. O. 87, Department of California, August 31, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the week ending September 5, 1885.*

Stewart, Henry, Surgeon. Leave of absence extended one year from October 15th, with permission to remain abroad.

Steele, John M., Passed Assistant Surgeon. Detached September 1st from Constellation, and to report for duty at Naval Academy, Annapolis, Md.

Bright, George A., Surgeon. Detached September 1st from Constellation, and to wait orders.

Dickson, S. H., Passed Assistant Surgeon. Ordered to Naval Academy, Annapolis, Md., as relief of Passed Assistant Surgeon A. A. Austin.

Fitts, Henry B., Assistant Surgeon. Detached from Coast-Survey steamer Gedney, and to wait orders.

Austin, A. A., Passed Assistant Surgeon. Detached from Naval Academy, Annapolis, Md., and ordered to Coast-Survey steamer Gedney, to relieve Assistant Surgeon H. B. Fitts.

Society Meetings for the Coming Week:

Monday, *September 21st:* Medico-Chirurgical Society of German Physicians (New York); Hartford City, Conn., Medical Association; Chicago Medical Society.

Tuesday, *September 22d:* New York Dermatological Society; Buffalo Obstetrical Society (private); American Gynæcological Society (first day—Washington); Medical Society of the County of Lewis (quarterly), N. Y.

Wednesday, *September 23d:* New York Pathological Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society (conversational); American Gynæcological Society (second day).

Thursday, *September 24th:* New York Academy of Medicine (Section in Obstetrics and Diseases of Women and Children); Harlem Medical Association of the City of New York; New York Orthopædic Society; Roxbury, Mass., Society for Medical Improvement (private); Pathological Society of Philadelphia (conversational); Cumberland County, Me., Medical Society (Portland); American Gynæcological Society (third day); New London County, Conn., Medical Society (extra—New London).

Friday, *September 25th:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Letters to the Editor.

WATER AS A LOCAL ANÆSTHETIC.

SEPTEMBER 16, 1885.

To the Editor of the New York Medical Journal:

SIR: My communication on the use and misuse of cocaine, as published in the latest number of this Journal, appeared, through an oversight of mine, minus a foot-note which, referring to the passage introduced by the word "*into*" (italicized, and occurring eight lines before the last one in the printed article), had been appended to the original manuscript.

Apropos of *cutaneous* as distinguished from *subcutaneous* injections, I would like to present now the statements which were to have been embodied, more briefly, in the foot-note.

1. The skin can be completely anæsthetized to any extent by cutaneous injections of water.

2. I have at times, of late, used water instead of cocaine in minor operations requiring skin incisions.

3. The anæsthesia seldom oversteps the boundary of the originally bloodless wheal, but does not always vanish just as soon as hyperæmia supervenes.

W. S. HALSTED.

NEWSPAPER NOTORIETY.

To the Editor of the New York Medical Journal:

SIR: Will you not give expression in the Journal to the sentiment of contempt so generally excited by the vulgar newspaper notoriety that appears to have been sought by several of the profession in the city during the last few months? Recent items, with which you must be familiar, have been so peculiarly offensive and numerous that the time for a public rebuke appears to have come. I hope your judgment will confirm this opinion, and that you will remind the offenders of the impropriety of their action, and warn them that notoriety is not reputation, or rather that it is reputation of a kind that can only do them harm.

If the matter concerned only the offending individuals, we might look on in silence at their vulgar vanity and their exploitation of "wonderful cases" or fortuitous connection with prominent personages; but, unfortunately, the profession is held to a measure of responsibility for the acts of its members, and upon each of us falls some portion of the contempt so freely expressed for them.

PRACTITIONER.

Proceedings of Societies.

NEW YORK OBSTETRICAL SOCIETY.

Meeting of March 17, 1885.

The Vice-President, Dr. B. McE. EMMET, in the Chair.

A Dilating Forceps.—Dr. W. T. LUSK showed a forceps, with narrow blades, which he had found very useful in several cases for the purpose of dilating the cervix.

Dr. E. L. PARTRIDGE thought it undesirable to employ blades which had so much spring, since there was danger of compressing the child's head unduly.

Dr. LUSK explained that he only aimed at dilating the cervix with this forceps, the delivery being subsequently effected with a different one.

Pyo-salpinx.—Dr. J. B. HUNTER resumed the discussion begun at the preceding meeting, presenting three additional specimens of pyo-salpinx. He gave the following *résumé* of the most important symptoms which he had noted: "In reviewing the cases of pyo-salpinx of which I have presented specimens to this society, and others which I have had opportunities of observing, I am inclined to think that there are certain symptoms and physical signs by which these cases may be distinguished, not only from those significant of ovarian disease, but also from other and less serious diseases of the tubes themselves. The symptoms common to suppurative disease of the Fallopian tubes I believe to be: Severe pain two or three days before menstruation, located in the affected side and running down the corresponding limb; constant pain during the menstrual period; comparative freedom from pain for a week or ten days after its cessation; profuse menstruation, and sometimes constant, though slight, metrorrhagia; a discharge of pus (having frequently an offensive odor) after the flow has ceased. The physical signs are: A mass is found posterior to the uterus, often so hard that it is mistaken for a fibroid tumor; the uterus is enlarged, globular in shape, and generally movable. When palpated after a period, the organ appears to be smaller than before, and the tumor behind it feels softer. There is often so much general tenderness around the uterus that an accurate examination is only possible during anæsthesia. In cases of hydro-salpinx (which it is important to differentiate from those of pyo-salpinx) the tubes are often much larger, and are, as a rule, freely movable, not being adherent to the uterus. Another point of difference between the two is that, while there may be a considerable amount of local pain in hydro-salpinx, there is not so much general disturbance as in suppurative inflammation of the tubes; in the latter case there is a marked deterioration of the patient's health from month to month. Doran, in his recent work on the ovaries and tubes, says: 'There can be no doubt that some of the most intractable cases of pain in the pelvic and iliac regions, often attributable to other causes, are really due to disease of the tubes.' The pain due to ovarian disease uncomplicated with tubal disease is of a more intermittent character, and is generally referred not only to the affected region, but also to the breast on the same side, and is very commonly accompanied by nausea—a symptom which is not noticed when the tube alone is affected.

"It is important to distinguish between catarrhal and purulent affections of the tube, because the treatment is radically different; cases of pyo-salpinx go on rapidly from bad to worse, and probably never recover without surgical interference, while simple hydro-salpinx, not complicated by serious ovarian disease, is not dangerous to life, and may remain stationary for years."

In conclusion, Dr. Hunter quoted recent statistics of Hegar's operations, which seemed to prove that the *ovaries* and not the *tubes* (as maintained by Tait) were actively concerned in the function of menstruation. Out of 134 patients (from a total of 149) who recovered from the operation there was a marked diminution of the size of the tumor, together with a cessation of the menses in 76 cases. It was certain that the premature menopause could not be effected by removal of the tubes alone.

Dr. WARREN asked if the speaker had not generally noticed a displacement of the uterus in his cases.

Dr. HUNTER replied that this was frequently, but not invariably, the case.

Dr. H. C. COE protested against the commonly received opinion that nearly all cases of pyo-salpinx could be traced di-

rectly to gonorrhœal infection. He thought that it was extremely difficult to trace this sequence, and was inclined to believe that many authors had simply copied their statements from others without taking the trouble to verify them. He had examined specimens of pyo-salpinx removed from unmarried females and from other patients in whose cases it was impossible to establish any previous specific affection; moreover, tubal disease was occasionally seen in animals, as had been shown by Mr. Sutton in his report of autopsies made at the London Zoölogical Gardens. As a rule, however, hydro-salpinx was the condition generally found in animals.

Dr. W. G. Wylie thought that a history of previous gonorrhœa could be obtained in many cases, but that post-puerperal septic endometritis was the most common cause of pyo-salpinx. He said that he had purposely kept cases of gonorrhœa under observation in order to see how they would terminate. In two instances undoubted peritonitis developed from a direct extension of the specific inflammation. A third cause was undoubtedly simple catarrhal inflammation of the uterine mucous membrane.

Dr. E. Noeggerath stated that there were, in all, five varieties of salpingitis, viz.: tubercular, syphilitic, actinomycotic, gonorrhœal, and septic. As regarded the most common cause of salpingitis, he did not propose to discuss its gonorrhœal origin, because those of the profession who formerly opposed his views most strongly had now accepted them, among others Hegar, Martin, Haeser, and many of the most prominent German gynæcologists. As regarded the variety to which Dr. Wylie had referred, and which he had designated as "septic salpingitis," Dr. Noeggerath said that many cases of salpingitis which followed premature delivery and were apparently of septic origin could be traced to a latent gonorrhœa, which had been the direct cause of the abortion. He cited a case in which a specific endometritis that had existed before pregnancy reappeared after delivery. He acknowledged that it was difficult to prove the causative relation in which gonorrhœa stood to pyo-salpinx, because the former disease, as communicated by the man, was always of a chronic nature, and therefore it was not easy to trace its beginning; in order to establish positive facts, a large number of observations must be made. "Suppose," said he, "we admit that septic salpingitis *does* arise from a purely septic endometritis; we do not know the true nature of the infection, because we are only just beginning to understand what puerperal septicæmia is." In order to prove the entity of a puerperal salpingitis, it would be necessary to trace the disease from the endometrium directly into the tubes; but this had not yet been done. A great change would be occasioned in the current views upon salpingitis if the characteristic gonococcus could be found in the morbid contents of the tubes. He had searched for it in the fluid from dilated tubes, but hitherto without success. He thought that, undoubtedly, other varieties of salpingitis would be discovered, due to the presence of other characteristic microbes. He had examined very carefully a drop of pus from one of Dr. Hunter's specimens, and had cultivated two varieties of micrococcus found in it, both of which resembled the gonococcus, but could not be considered as identical with that microbe. It was possible that the coccus of gonorrhœa might change its characteristic form after entering the tube, since it was then in a new soil and subject to new influences; but this intricate matter could not be settled without a large number of observations.

In reference to the matter of diagnosis, Dr. Noeggerath referred to a remark made by Dr. Wylie at the preceding meeting, that it was not necessary to make out the actual presence of enlarged tubes in order to justify an operation, provided the local symptoms were sufficiently urgent.

He showed an instrument which he had found useful in cases in which it was desirable to make an exact diagnosis. It consisted of a double hook opening outward, one arm of which terminated in a long extremity resembling a uterine sound. The sound was introduced so far into the uterine cavity that the hooks were half an inch within the cervix; the uterus was then pulled downward by an assistant, while the surgeon, with one finger in the rectum and the other hand upon the abdomen, could thoroughly explore the pelvis. The uterus could be moved toward or away from the examining finger, and the appendages could be more perfectly examined than in any other way. If necessary, the urethra could be gradually dilated (the process being repeated two or three times a day for two or three weeks) until the forefinger could be passed into the bladder, when the ovaries and tubes could be plainly felt. It was sometimes very important to be able to make an exact diagnosis, because it made a great deal of difference in the prognosis of an operation whether the tubes were much diseased or were unaltered themselves, but were surrounded by inflammatory adhesions. In the former case the prognosis was good, but where the symptoms were due to other causes than diseased tubes or ovaries it was unfavorable. If, however, there was a history of a subacute peritonitis which had become chronic, one could infer, in nearly every instance, that the tubes were diseased and that an operation was necessary. Disease of the tubes was the *cause*, and not the *result*, of the perimetritis. There were peculiar conditions in individual patients which it was important to recognize; as an example, he cited the case of a lady who had an attack of acute perimetritis six years ago, and had been under treatment ever since. He examined her six months ago by the method before described, and found both ovaries atrophied, the tubes being only slightly enlarged, but buried in a mass of adhesions, whereupon he refused to operate. It was in such a case as this that the instrument devised by him had proved most useful.

Dr. Wylie had not wished to give the impression that he did not try to make an exact diagnosis in cases of enlarged tubes; on the contrary, he always made a practice of keeping his patients under observation for weeks, or even months, before operating, so that he was frequently enabled to clear up the inflammatory deposits sufficiently to ascertain the precise condition of the appendages. He disapproved of the practice of pulling down the uterus for diagnostic purposes in these cases, or even of passing a sound into the cavity, since there was great danger of lighting up peritonitis. By anæsthetizing the patient and passing the left forefinger into the rectum, he could ordinarily map out the pelvic contents and detect any enlargements in the broad ligaments. In some instances he could not decide whether the tumor was an enlarged ovary or a tube. (Specimens were shown illustrative of this difficulty.)

Dr. Hunter agreed with Dr. Wylie in his disapproval of forcibly depressing the uterus. To illustrate the difficulty which was sometimes experienced in diagnosticating pyo-salpinx he mentioned a case in which several experienced gynæcologists had pronounced as a fibroid a pelvic enlargement which proved, on operation, to be a dilated tube filled with pus. He asked Dr. Wylie if he had ever seen a case of pyo-salpinx in which the tube was not adherent.

Dr. Wylie had seen only one such case; as a rule, the tubes were prolapsed and adherent posteriorly to the uterus or to the pelvic floor. When the tubes were not prolapsed, their fimbriated extremities were generally adherent to the uterus.

Dr. Lusk asked if it was necessary to remove both ovaries and tubes in Tait's operation. He had left a tube and ovary in two cases with subsequent bad results.

Dr. Wylie and Dr. Hunter had each had a similar experience, the disease being confined to one side.

The Chairman asked Dr. Noeggerath whether it was common for only one tube to be involved in gonorrhœal salpingitis.

Dr. Noeggerath replied that unilateral pyo-salpinx was very rare, so that he could not say how often this condition prevailed in specific cases. Reasoning from analogy, he could see no reason why the disease should not be limited to one side, since one epididymis frequently became involved as a result of gonorrhœa in the male, the other being spared. If there was any doubt as to the existence of pyo-salpinx at the time of operation, he believed that the surgeon was justified in squeezing out a drop of the secretion of the tube from the fimbriated end. He mentioned a case in which a woman had died of acute peritonitis in twenty hours after receiving a severe mental shock. On autopsy, both tubes appeared to be healthy, but a small amount of sanguineous fluid could be pressed from them, which, on microscopical examination, proved to be identical with similar fluid found in the pelvis. The contents of one tube escaping into the peritoneal cavity had undoubtedly led to the fatal result.

Dr. Wylie questioned whether the chronic peritonitis which was present in cases of pyo-salpinx was due to the condition of the tubes or *vice versa;* he thought that the diseased tubes probably acted as inflammatory foci.

Dr. Lusk recalled a case of peritonitis developing on the second day after a normal labor, and terminating fatally in forty-eight hours. At the autopsy nothing abnormal was found except an inflammatory condition of the tubes, the precise nature of which he could not recall; there was a possible element of latent gonorrhœa in the case, as the husband was treated for a stricture and gleet before marriage.

Dr. B. F. Dawson also remembered a case of acute peritonitis in a young woman which terminated fatally, the tubes being found at the post-mortem to be full of pus.

Puerperal Septicæmia.—Dr. Wylie reported a case of fever, which developed on the fifth day after delivery, which he attributed to a diphtheritic process in the uterus, because regular pseudo-membranous masses came away during the injections. He found that by using intra-uterine injections of sublimate solution every hour the temperature could be brought down to normal, but when the treatment was discontinued for two or three hours it speedily rose to 104° F. He did not see why a diphtheritic inflammation could not extend to the tubes.

Dr. Noeggerath believed that puerperal endometritis was frequently diphtheritic in character. The elder Martin had gone so far as to say that all these cases were diphtheritic, but this was too sweeping an assertion. Dr. Noeggerath had observed three cases in which pseudo-membranous casts of the uterine cavity were discharged.

Dr. Wylie, in reply to a question from Dr. Hunter, said that a solution of carbolic acid (1 to 60) brought away sloughs and controlled the temperature much better than the sublimate solution (1 to 5,000). Quinine had been used absolutely without effect. He remarked in conclusion, with reference to the objections to Tait's operation, that there were undoubtedly many patients whose local condition improved so much under treatment that an operation became unnecessary; he agreed with Dr. T. A. Emmet that this experience was a very common one in practice. It seemed to him, too, that it was often possible to remove the results of a previous peritonitis by appropriate treatment without operations.

Dr. Noeggerath insisted on a line being drawn between perimetritis and parametritis, the presence of the latter condition being a distinct contra-indication to laparotomy. He thought that the term "cellulitis" should be abandoned as a relic of the old speculative pathology. Parametritis, as a rule, was only present as a result of some lesion of the uterus (puerperal or otherwise), but not in disease of the tubes, the latter being accompanied by perimetritis.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of September 9, 1885.

The President, Dr. John A. Wyeth, in the Chair.

Vesicular Mole.—Dr. H. J. Boldt presented the specimen, which was principally interesting as illustrating the extremes to which a patient might be reduced by a remediable condition. The woman, who had been flowing profusely for several days, had become very anæmic, and the pulse was almost imperceptible. A physician had employed a tampon, but without benefit. Dr. Boldt found the os dilatable but not dilated. He at once introduced a sponge-tent, dilated the canal, and found a vesicular mole slightly adherent to the fundus and sides of the uterus. The patient probably would have died within twenty-four hours had the growth not been removed.

Coincidence between Vaccine Inoculation and the Development of Bone Abscess.—Dr. W. P. Watson presented a girl five years of age who had always been well until two years of age; the family history was also good. When two years old the child was vaccinated, not by a physician, but by a man who had vaccinated many other persons, so far as known without injurious effects. In the case of the girl presented two incisions were made below the deltoid, which bled profusely; it was not known whether the matter used was animal or human. A few days after vaccination the mother noticed a swelling on the outer aspect of the left forearm, which was very much inflamed by the sixth day. A week later a swelling appeared on the right arm in a similar position; two weeks later there was one over the left scapula, and two months later one on the outer aspect of the right leg. Unhealthy pus discharged from some of the abscesses for two years, and several spiculæ of bone came from the sinus on the left forearm. The sinuses were now entirely closed, but there was ankylosis at the left elbow-joint. The axillary glands enlarged but did not suppurate. The question arose, Was there any causative relation between vaccination and the development of the abscesses? The mother very naturally attributed the trouble to vaccination.

Dr. Boldt asked whether the child might not have sustained an injury after it had been vaccinated. [The mother replied in the negative. There were an erysipelatous eruption and swelling at the point of vaccination, which, however, were simultaneous in appearance with the swelling on the left forearm.] Dr. Boldt then related the case of a child whom he had vaccinated, and in whose case multiple abscess developed. The mother denied that any traumatism had occurred, but it was learned that one day during her absence from the house the child sustained a slight injury, which was followed by an erysipelatous eruption and bone abscesses.

Idiopathic Nephritis in Infants.—Dr. J. Lewis Smith presented some specimens from the body of a child which had died, aged seven months. It had been fed by a wet-nurse, and was seen by Dr. Smith only a few times during the course of its illness. It had done well until nearly six months of age, when the mother called attention to the fact that it had not passed urine for some hours. Some sweet spirits of niter restored the secretion. As bearing upon the ætiology, he said there had not been any case of scarlet fever or diphtheria in the institution recently. Five days later the urine was again suppressed, but was restored by the same medicine. The child

then did well for about eleven days, when diarrhœa occurred. After the second day the passages did not exceed four in number during the twenty-four hours, but the child did poorly, and died September 1st. August 2d it had general convulsions lasting five minutes. Following the convulsions there were marked nervous symptoms lasting three days, and a constant rolling of the head on the pillow afterward. During the last two weeks of life the child had occasional cough. During August the morning temperature was usually about 100° F., the evening temperature two or more degrees higher, the highest temperature reached being 106° F. The lesions of special interest were in the kidneys. The organs were much enlarged; the cortex of the right kidney was thickened; the pyramids were congested; the mucous membrane lining the calices and pelvis was deeply congested. The left kidney was intensely congested, the pyramids and cortex being of one color. The capsules were not adherent. The bladder showed catarrhal inflammation. The urine found in the bladder contained mucus, a large amount of albumin, and hyaline, granular, and epithelial casts in abundance; mucous corpuscles and red blood-corpuscles were present. Dr. Dana, who made the autopsy, attributed death to acute nephritis. The case was interesting as going to show that idiopathic nephritis might occur in the young infant, a fact almost universally overlooked. [The specimens were referred to the Microscopical Committee.]

Dr. Boldt had that day made an autopsy in the case of a child which had had diarrhœa for three months. There was suppression of urine the day before death. The temperature reached 108·3°. Acute nephritis was found to exist. The child was thirteen months old at the time of death.

Perforating Ulcer of the Duodenum.—Dr. Frank Ferguson presented two specimens, the first consisting of the duodenum perforated by an ulcer, the base of which was circular and nearly an inch in diameter; the upper surface was triangular in form. The patient was a tailor, forty-five years of age, who was unable to speak English or to give a full account of his symptoms. It was learned, however, that he had been sick for a month, complaining of pain in the stomach and constipation. On admission, he was emaciated, and the abdomen was tender and retracted. He vomited several times. The temperature remained between 100° and 105°; the pulse was 82; the urine was negative. Death took place two days after admission. Dr. Ferguson remarked that he had seen three cases of perforation of the duodenum, and in all of them the peritonitis had been of a type not easily diagnosticated. He thought the peritonitis had probably existed a month and a half or two months. Aspiration, perhaps, might throw some light on the diagnosis. The danger of perforating the intestine with the needle he thought was not great.

Cardiac Dilatation and Hypertrophy; Perforation of the Inter-ventricular Septum; and Vegetations on the Aortic, Tricuspid, and Pulmonary Valves.—The second specimen presented by Dr. Ferguson was the heart of a boy, thirteen years of age, who had probably had rheumatism. He also suffered from difficult breathing and slight general anasarca. The sternum and the jugular veins were prominent; the cardiac area was increased; the apex beat could not be felt; there was a distinct epigastric impulse. There was a loud blowing thrill in the seventh intercostal space, on a line with the nipple, transmitted to the left; in the second intercostal space, just to the right of the sternum, was a double systolic murmur, transmitted upward. Before death the respiration and the pulse became very rapid. At the autopsy the lesions of chief interest were found in the heart. It was dilated and slightly hypertrophied, and there were vegetations on the aortic, the tricuspid, and the pulmonary valves. There was an opening through the inter-ventricular wall, and it was not improbable that vegetations from the left side of the heart had found their way through this opening into the right side. At any rate, vegetations in the right heart were seldom seen. There was no history of embolism.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of September 3, 1885.

The President, Dr. B. F. Baer, in the Chair;
Dr. W. H. H. Githens, Secretary.

Ovarian Cystoma complicated with Peritonitis and Phlegmasia Alba Dolens; Double Ovariotomy.—The President read the following report of a case:

"Mrs. M., aged thirty-one, has been a widow nine years. She had one child ten years ago, and had enjoyed good health until about three years before I saw her. At that time she observed that her abdomen was increasing in size. This gradually progressed for eighteen months, when she was large enough to attract the attention of her neighbors. After this the growth remained almost stationary, and did not affect her general health until the latter part of March of the present year, when she was suddenly seized with pain in the left iliac region. The pain was acute and radiating in character, extending principally down the anterior portion of the left thigh. She attributed the attack to an unusual exertion. Although she made an effort to continue her avocation —that of a seamstress—she was compelled to give up and send for her physician, my friend, Dr. John R. Haney, of Camden, N. J. When Dr. Haney first saw her, her abdomen was very tender over its entire surface, purple from congestion, greatly distended, and tympanitic in its upper, but dull in its lower, portion. She was suffering great pain, and had constant nausea and vomiting; her skin was hot, pulse 120, and temperature 130° F. From the history, symptoms, and physical signs elicited, the doctor diagnosticated ovarian cystoma, with supervening peritonitis. He administered quinine *per rectum* and morphine hypodermically, and employed counter-irritation over the abdomen. Within a week the patient appeared to be better, when, through the kindness of Dr. Haney, I first saw her. The tympanites had disappeared, and the pain was not so severe, but the abdomen was still very tender on pressure, especially in the left iliac and right umbilical regions; her features were drawn and flushed, and presented an anxious expression; her tongue was dry and heavily coated, her pulse quick, and her temperature 102° F. She lay quietly in the dorsal position, with her thighs flexed. The abdomen was as large as at full term of gestation, and was projecting. It was dull on percussion everywhere, except along the line of the colon and in the epigastrium, and there was evident fluctuation. The uterus was retroverted, not freely mobile, and very tender on pressure on the left side. Above and upon it could be felt the lower border of the circumscribed growth which occupied the abdominal cavity. I fully agreed with Dr. Haney's diagnosis of ovarian cyst, complicated by peritonitis. As she seemed to be somewhat better, I advised a continuance of the treatment as previously pursued, with the hope of obviating the necessity of ovariotomy during the unfavorable condition in which she then was. The peritonitis continued to improve slowly, but a new trouble presented itself in a very painful swelling of the left lower extremity. This continued until the limb was greatly increased in size. Its temperature was much higher than that of its fellow, which seemed to be in a normal condition. She now required large doses of morphine to relieve her pain, and she was losing flesh and strength. She still had nausea, and took scarcely any nourishment. Her temperature and pulse had again risen to the highest point noted. Both she and her friends were willing and anxious that we should do something more radical than simply wait for a more favorable condition for operating if we deemed it proper. I believed, from the symptoms and physical signs, that the inflammatory action was external to the cyst and not within it, and for that reason decided to wait for a subsidence of the acute symptoms, which I rather confidently expected. At the same time I held myself in readiness to operate at once should the patient not improve or become worse. The next

day she showed signs of slight improvement. The treatment, both local and general, was continued. The acute symptoms gradually subsided to those of a subacute condition. The temperature had decreased to 101° F., the pulse was 100, but weak. She was still unable to retain food, and was extremely weak. I advised further delay. But she did not improve much after this, her temperature and pulse remaining about the same as that noted above. Her stomach had regained its power to a slight degree to retain and digest liquid food. She had now been confined to her bed more than two months. Her left leg was powerless. There had not been the slightest improvement during the two previous weeks. We therefore decided to remove the tumor.

"*Operation.*—June 19, 1885, assisted by Dr. J. R. Haney, Dr. W. A. Davis, and Dr. H. M. Christian, and in the presence of a section of the class from the Polyclinic, I made an incision three inches in length down to the peritonæum, and then checked the hæmorrhage, which was free, with clamp forceps. I next very carefully incised the peritonæum and found, as I had expected, that it was closely united to the cyst-wall. These adhesions of the cyst to the peritonæum were universal, and it required careful and patient manipulation to separate them. The parts were exceedingly vascular and the hæmorrhage was profuse. After separating it as far as possible, I tapped the cyst and allowed the contents, which were semi-liquid and chocolate-colored, to drain away. I next closed the puncture made by the trocar, and then completed the separation of the cyst from its adhesions and removed it. As there was a very general and free oozing of blood from the broken vessels, I introduced a number of large, flat sponges, and spread them over the bleeding surface. An assistant now made firm pressure upon the external surface of the abdominal walls, while I ligated the pedicle and removed the tumor. The cyst had developed in the left ovary, and the pedicle was slender, not unusually vascular, and of good length. The right ovary was diseased, containing a number of small cysts, and was of double the normal size. I removed it also. Examination now showed that the hæmorrhage had almost ceased, but there were still a number of points from which blood flowed. The peritonæum was intensely injected, and I disliked very much to pick up bleeding points for fear of making the hæmorrhage worse. I therefore reapplied a large flat sponge, and had firm pressure again made from without, while I proceeded to place the sutures for the closure of the incision. I then removed the sponge and found very little blood upon it. I replaced it by a long narrow strip of sponge, which I allowed to project from the lower angle of the wound, and then again cleansed Douglas's *cul-de-sac* and other dependant portions of the peritoneal cavity, after which I quickly tied the sutures from above downward, removing the long sponge through the lower angle of the wound before I had encroached so closely upon it as to compress it in its removal. It was only slightly stained. I quickly applied the external dressing, making an unusual amount of pressure by cotton and bandage. The operation was finished, but the patient bore it badly. Her extremities were cold and purple, her face livid, and her pulse very weak. Stimulants hypodermically, and the application of external heat, which were begun during the operation, were continued after she was returned to bed. She remained in an almost collapsed state for many hours, but gradually reacted, and the next morning was in a fair condition. Her temperature was lower than it had been for weeks; pulse 112, but weak; stomach quiet, no pain, no tympany. She had taken an occasional small piece of ice, but nothing else except the morphine since the operation.

"*21st.*—Temperature 102°, pulse 120. Slight pain and tenderness in the left iliac region. She had been very weak and faint during the night, for which brandy had been administered in repeated small doses. The swelling and pain in the limb had diminished; she had not vomited since the operation, and felt hungry. Ordered a teaspoonful of milk every second hour.

"*22d.*—Comfortable and doing well. Temperature 99·4°; pulse 90 and strong; slight metrostaxis; passed flatus *per rectum*. Milk increased to a tablespoonful and retained.

"*24th.*—Temperature 99°, pulse 85. General condition greatly improved; no pain, no tympany. Examined the wound and found it united throughout; removed the sutures.

"*25th.*—Doing well, and is bright and cheerful. She has taken nearly a quart of milk during the last twenty-four hours, and digested it.

"*30th.*—She has been gradually improving. Temperature normal, pulse 95; bowels moved to-day. She is taking solid food and expresses herself as feeling quite well. Limb improving. She can now move it.

"*July 12th.*—Sat up to-day for the first time, the twenty-second after the operation.

"*August 30th.*—A note received from Dr. Haney to-day informs me that Mrs. M. is going about attending to some of her duties, but that she has not yet regained her strength fully, and that her limb is still weak.

"The recovery of this woman under the forlorn circumstances just narrated is certainly a great triumph for our art; but the case serves a better purpose in forcibly illustrating the danger of deferring operative interference in ovarian cystoma simply because the patient is comfortable and suffering no inconvenience from the presence of the tumor. The subject of an ovarian tumor is in constant danger of injury from slight causes which may produce such changes in the tumor as to render what might have been a simple and safe operation one of extreme hazard. This had been a simple, slow-growing cyst, and had not markedly affected the health during its three years of existence; yet it suddenly became inflamed and the patient narrowly escaped death as a result. The case furnishes a strong argument in favor of operation as soon as the disease is diagnosticated. Of course there are qualifications, and each case must be decided on its own merits; but the rule that an ovarian tumor should be removed as soon as it is known to exist is the only safe one to follow."

Polycystic Ovarian Tumor; Double Ovariotomy.—"As a striking contrast to the case just related, and to show the value of the principle enunciated," continued the PRESIDENT, "I will report the following case:

"A. R. was sent to me August 5, 1885. She was nineteen years of age; single. Puberty was established at sixteen, and she had menstruated regularly until six months previously. She then without cause, so far as she knew, began to flow more freely at her periods and they continued longer. About the same time she noticed a small lump in the right iliac region. This increased in size so that soon the entire hypogastrium was distended, and when I first saw her she was as large as a woman at the eighth month of gestation. Her face showed marked signs of emaciation and pallor, and the drawn, anxious expression of ovarian cystic disease. She was then having a profuse metrorrhagia every two weeks. She had not suffered any pain, and up to within a few weeks very little inconvenience, except from the frequent metrorrhagia. During the last month, however, her health had been failing, she had lost flesh, had a weak, languid feeling, and suffered much from the weight of the growth. Physical examination in the dorsal position revealed a projecting, slightly irregular abdomen, larger on the right side, dull on percussion over the entire anterior surface, but resonant along the line of the colon. Palpation showed imperfect fluctuation and several firm, irregular masses within the abdominal cavity. The vagina was virginal, the cervix uteri was pointing forward, the body of the uterus retroverted, the whole organ enlarged and soft. It was only slightly movable independently of the tumor. The sound gave a measurement of three inches.

"I diagnosticated polycystic disease of the right ovary, and advised immediate operation. Six days afterward, on August 11th, she entered my private hospital, and on the 13th I operated, with the assistance of Dr. H. M. Christian and Dr. J. N. Richards. I made an incision two inches and a half in length and came upon the surface of the tumor, which presented the white, glistening, nacreous appearance especially common to thick-walled polycysts. I tapped it with Hodge's trocar. The contents were so thick that they flowed very slowly, and it was necessary to puncture several smaller cysts, which was done without removing the instrument. Even then the mass did not collapse much, because of a large number of young or child-cysts. After closing the puncture I enlarged the incision to three inches, but I had considerable

difficulty in removing the tumor. It was necessary to make firm traction with rotatory movements while Dr. Christian exerted a counter-force and pressure through the abdominal walls. Fully ten minutes were occupied in extracting the tumor after it was tapped, but I was rewarded with an incision that looked so small that it seemed almost incredible that this large mass had passed through it. There had not been a single adhesion, but the pedicle was short, thick, and vascular. I tied it with Tait's Staffordshire knot, cut the tumor away, and dropped the stump. The tissues of the left ovary were found to be entirely disorganized and degenerated into a cyst as large as a walnut. This I also removed. The uterus presented a very vascular appearance and was somewhat enlarged. After assuring myself that the peritoneal cavity was entirely free from any foreign matter, I closed the incision, dressed the wound, and returned the patient to bed. Her temperature was normal, and her pulse 96. There was no pain, but, as she felt a little sore and restless, a quarter of a grain of morphine was given hypodermically, and she took small pieces of ice for thirst.

"*14th.*—8 A. M. Temperature 99°, pulse 84. Had passed a good night. At 1 P. M., twenty-six hours after the operation, milk in teaspoonful doses was allowed, and water when she desired it.

"*15th.*—Metrostaxis began this morning.

"*18th.*—Union complete; removed the sutures. Her recovery was uninterrupted. She sat up for a few minutes on the eleventh day and went home, eight miles, in a carriage on the eighteenth day after the operation. To-day she sent a request to be permitted to go out, because she was feeling so well.

"Certainly nothing could have been gained by procrastination in this case."

Dr. Goodell congratulated the president on the good result obtained in such a serious case as that first reported. Great care as to asepsis should be observed in these cases. In one of his cases of septicæmia before the operation, after complete union had been secured, after the stitches had been removed, and after the patient was up, an abscess was observed forming in the line of union and was very persistent. Finally, after careful search, a ligature which had been tied around the pedicle of one of the ovarian cysts was found and removed. Subsequently the other appeared, and, after its removal, the abscess healed. He did not like to remove the stitches so early as the president removed them; and he reminded him of a case in which he had assisted him (Dr. Goodell). The operation was performed on December 5th. Convalescence was rapid, and the patient was so impatient to be home on Christmas that she could not be restrained, and on the nineteenth day after the operation she took the cars for home. The train was derailed and the jolting caused the cicatrix to open. The physician who was called in closed it immediately and the patient recovered In another case a cough caused the wound to burst open and reveal the bowels after the stitches had been removed. This patient also recovered. For these reasons he never removed the stitches before the eighth day and not until the bowels had been opened. The speaker inquired of the president what his method was of closing the opening in the cyst after it had been tapped preparatory to its removal from the abdominal cavity. Did he employ pressure forceps? What method did he use of dressing the abdominal wound?

The President closed the cyst puncture with Wells's clamp-forceps when the cyst-wall was strong enough. In some cases he stitched up the opening, or tied a string below it when the cyst-walls were loose and soft. He closed the external wound, as he had been taught by Dr. Goodell, with silk sutures, and dressed it with salicylated or absorbent cotton, adhesive strips to hold the cotton in place and take the strain off from the stitches, and over all a bandage. He removed the sutures on the fourth or fifth day in order to avoid the danger of pus forming in the suture-tracks, as had sometimes occurred when he had allowed them to remain as long as eight days.

A Uterine Dilator.—Dr. Goodell exhibited his improved uterine dilator. He said that the main difficulty in the operation for the rapid dilatation of the cervical canal lay in the liability of the blades of the instrument to slip out. This he had in a great measure overcome by having shallow grooves cut into them. Into these grooves the tissues sank, and the resulting friction kept the instrument in place. Since he had called the attention of the society to his instrument, not quite a year ago, he had performed the operation forty-one times for dysmenorrhœa and sterility, making in all two hundred and nine such cases. In not a single instance had dangerous symptoms followed, and the average of success was a very large one. He had become firmly convinced that for dysmenorrhœa and sterility the operation of rapid dilatation of the cervical canal would, except in some very rare cases of stenosis of the os externum, wholly supersede the cutting operation, the use of tents, and slow dilatation by any means whatever; for by the former not only was the measure of success far greater, but the danger from inflammation was very much less. He dilated the parts from three quarters of an inch to one inch and a quarter as measured off by the register in the handles, watching the cervix carefully to see what strain it could bear. His instrument could be opened to the width of an inch and a half, but he resorted to that extreme divergence only when wishing to introduce his finger for diagnostic purposes. This he could not ordinarily do unless the parts were relaxed from hæmorrhage. Usually, however, when suspecting the existence of a polypus, he did not find it needful to pass in his finger, for after a moderate dilatation he introduced a fenestrated forceps and opened it at hap hazard. In this manner he had repeatedly caught and twisted off a polypus without knowing it was present, the subsequent removal of the growth through the os uteri being the most difficult part of the operation.

The President had been strongly impressed, by the case of a lady whom he had delivered to-day, as to the advisability of entirely giving up division of the cervix. A year and a half ago he had slit up the cervix posteriorly, and to-day he had felt very anxious during the first stage of labor as to the probability of laceration of the uterus starting from the seat of the former operation. The anterior lip was very long, coming down under the bubes, and the posterior lip could not be felt. The case would be reported in full.

When the uterus contained a polypus the continued hæmorrhages reduced the contractility and a single dilatation would sometimes enlarge the os sufficiently to admit the finger or forceps; but, if the uterus was healthy, it contracted immediately after the withdrawal of the dilator. He could not recall an instance of inflammation following rapid dilatation. Sterility of long standing was seldom cured by dilatation or any other means.

Dr. C. M. Wilson had seen recently, in the practice of Dr. Ellwood Wilson, a uterus the cervix of which had been divided bilaterally some years ago. The operation had resulted in the development of the symptoms peculiar to a bad laceration of the cervix, with ectropion. Trachelorrhaphy was performed by Dr. Agnew, with complete relief to the patient. Dr. Wilson mentioned this case to call attention to the change in opinion and practice since Emmet proposed his operation.

Dr. Longaker inquired as to the prevention of slipping of the dilator, and called attention to the original method of pressure over the fundus of the uterus.

Dr. J. G. Allen had performed rapid dilatation over seventy-five times, and had never seen any bad results from the operation. The blades of his instrument diverged as they separated, and there was then no disposition to slip out. The blades were more curved than in Dr. Goodell's instrument. He thought

that an advantage in holding the instrument in place; the handles were turned up so as not to touch the bed or table.

Dr. Goodell preferred the slight curve, so that in flexion of the uterus he could introduce the dilator with its curve reversed to the bend in the womb, and, by opening the dilator in that position, rectify the flexion of the organ. He preferred parallelism of the blades because the stenosis of the cervix was greatest at the external os, and there was no need of dilatation above the internal os. He considered it dangerous to press the fundus of the uterus down while using the dilator, for fear of wounding or even penetrating the tissues, and he used a strong tenaculum to hold the organ; but, since he had got Mr. Gemrig to roughen the blades by grooves, he had not been annoyed by the slipping of the instrument. He rarely found it necessary to separate the blades more than one inch, but he sometimes did so to the extent of one inch and a half, especially when he wished to introduce his finger into the uterine cavity.

Parovarian Cysts.—Dr. Goodell exhibited two specimens. In each case the cyst was so detached from the ovary that the former could have been taken away without injury to the ovary. He was greatly tempted to practice conservative surgery in these cases, and leave the ovaries untouched; but, on account of apparently incipient cystic degeneration, they also were included in the ligature and removed. Both these patients were operated on in his private hospital, and both had recovered. In his experience the removal of parovarian, or of broad-ligament, cysts was one of the most successful of operations. Out of a large number which he had performed he could recall but a single fatal case, and in that the result seemed hardly due to the operation. The lady lived in a distant city, and he did not see her after the operation, which was a very easy one. At the end of a week the bowels were moved, the stitches removed, and everything gave promise of an unusually prompt convalescence. On the twelfth day, however, she was seized with uncontrollable vomiting, and she died on the seventeenth day. Six months previously she had had an analogous attack of vomiting, from which she barely escaped with her life. Thus far this year he had had eighteen ovariotomies, and this was the only fatal case among them.

Dr. Montgomery wished to ascertain the opinion of the society as to the advisability of removing the second ovary when in an operation for the removal of an ovarian cyst the other ovary was found to be slightly diseased. In his first ovariotomy, performed in 1879, the second ovary was found to contain numerous small cysts; it was not removed, and the patient had since been twice pregnant and there had been no appearance of another tumor, nor any symptoms referable to the remaining ovary. If the climacteric had been passed there would be no question about it.

The President inquired if tapping ever cured parovarian cysts. It was formerly reported as a means of cure. Did they always return after tapping? Would Dr. Goodell recommend tapping in undoubted parovarian cyst? He himself felt strongly inclined toward abdominal section in all cases. He thought the second ovary should be removed when it was not healthy, as the idea of a second operation was very depressing to a patient.

Dr. Montgomery knew of one instance of parovarian cyst which had been tapped and had refilled seven times. It was finally removed by him by pulling out the cyst, as, on opening the abdomen, he found the tumor universally adherent. Only one ligature was required—viz., on the stump of an enlarged ovary which bulged prominently into the cyst cavity.

Dr. J. G. Allen considered that, as an ovary somewhat diseased might give rise to a pregnancy, it should be left. We knew too little about the probability of the development of such small cysts into large ones. Until we had certain data on the subject it must be considered a case of want of information and knowledge.

Dr. Parish was in accord with Dr. Allen as to the want of knowledge. He had seen diseased ovaries containing numerous small cysts in many autopsies, and there had been no symptoms during life to excite a suspicion of their existence. The existence of minute cysts could not be considered as proving any liability to the production of large ones. If the second ovary contained a cyst as large as a partridge's egg he would remove it, but if numerous cysts as small as split peas were present he would not. The possibility of conception should be considered as well as that of a cyst.

Dr. Goodell acknowledged the truth of the points made by Dr. Allen and Dr. Parish, and he believed that he had repeatedly removed the second ovary unnecessarily. Yet the history of his own ovariotomies showed a return of the disease in the remaining ovary in about two per cent., and he thought he erred on the safe and right side. The social conditions of the patient would always have a great weight with him. If an heir was wanted or the patient was young, he would leave a suspicious-looking ovary, or try to remove the diseased portion of it. But in the majority of his cases where there was any doubt he removed the ovary. Of course, under such a rule, he must remove ovaries which might never give any trouble in the future. But the mental agony of women when informed that the operation must be performed a second time upon them, and, on the other hand, the great joy and satisfaction of patients when assured, after the close of an operation, that both ovaries had been removed, had convinced him that, other things being equal, it was better to remove the second ovary.

As to the cure of parovarian cysts by tapping, his own experience was not sufficient yet to decide absolutely. He would advise the radical operation, but if the patient, after understanding the liability of return, wished it, he would tap, as there was but little danger from tapping such cysts. A patient was tapped by Dr. Atlee some twenty years ago; five years afterward the cyst filled and was tapped by the speaker. It then partly refilled and so remained for a long while; the fluid then was gradually absorbed and never returned. He had had besides this one two cases in which he tapped, one five years ago and the other three years ago, and there had been no return whatever of the fluid. On the other hand, he had had two or three cases in which the cyst burst spontaneously several times and yet refilled invariably. The rupture was followed immediately by some collapse and pain, and subsequently by an excessive secretion of urine, with complete subsidence of the tumor. He had also heard of several cases of rupture, but, so far as he had learned the history of such cases, the cyst had always returned. The reports of the cure of ovarian cysts by tapping and injection of tincture of iodine must be true only of parovarian cysts.

Dr. Harris knew of a case of parovarian cyst in which fourteen years had elapsed between the tapping and the subsequent refilling.

Bromide of Ethyl.—Dr. E. E. Montgomery read the following *supplement* to his paper: "I read a paper on bromide of ethyl as an anæsthetic in labor before the April meeting of this society. Although I did not attempt a history of the early administration of the drug, subsequent investigation has shown me that I did Dr. L. Turnbull injustice in not mentioning that to him we are indebted for the revival of this agent and its first use in this country. In following the German literature, by which I was led to use this drug in labor, I ascribed its first obstetrical use to Lebert, of Paris. The first case in which he used it was for the application of the forceps, and occurred in March, 1881; but a paper published by Dr. Turnbull ('Med. Bull.,' June, 1880) shows that he had then used it in a second

case of labor, and spoke in high terms of its peculiar advantages. Dr. H. Augustus Wilson had used it in labor prior to August 7, 1880, when he published an article upon this drug ('Med. and Surg. Rep.,' August 7, 1880). It becomes quite evident that the first obstetrical trial of this agent was made in this city, and the priority lies between the gentlemen named. Various mixtures of the ethyl have been advocated in labor and minor surgical operations. Booth, of Ohio ('Therap. Gaz.,' 1884–'85, p. 159), recommends alcohol two parts, chloroform and bromide of ethyl, each one part. W. A. Byrd, of Quincy, Ill. (*Ibid.*, March, 1884), has used bromide of ethyl one part, chloroform three parts, alcohol four parts, in some ninety-eight cases without a single unpleasant symptom. It has not everywhere received the same condemnation that is shown by the hesitancy to use it in this city. In spite of the bad name given it by two deaths under its use and the apparently dangerous symptoms induced by experiments upon the lower animals, its use has been revived by Chisolm ('Maryland Med. Jour.,' 1882–'83, ix, 388) and Prince ('St. Louis Med. and Surg. Jour.,' 1883, xiv, 297), who strongly urge its use in minor operations, and preliminary to the administration of ether. The last named has reported five hundred cases in which it was used without a single unpleasant symptom. A leading article in the 'Therapeutic Gazette,' June, 1885, advocates a redistillation of a mixture of bromide of ethyl and olive-oil as a valuable and safe anæsthetic in labor. These facts are referred to simply to induce the profession to give this anæsthetic a fair trial in ameliorating the terrible suffering of natural labor."

Fibroid Polypus of the Uterus.—Dr. Montgomery exhibited a uterine fibroid polypus. Miss R., aged thirty-eight years, began to menstruate at seventeen years. The flow was regular, quite free, lasting a week, and was attended with pain the first three days. Ten years ago she had a hæmorrhage, and subsequently several such attacks. Two years later she had a severe hæmorrhage followed by a bloody discharge continuing several months, since which time she had never been regular. The flow would occur too frequently, be very profuse, and be attended with pain and loss of flesh. The symptoms had been more marked during the last year. At one of the hospital clinics, some years ago, the difficulty was ascribed to anteversion of the womb. Dr. Bournonville examined her three weeks ago, diagnosticated the condition fibroid polypus, and referred the case to the speaker for treatment. She was quite pale, her lips were bloodless, and she complained of pelvic pain and of a constant bloody discharge, which amounted to hæmorrhage upon the slightest exertion. The vagina was dilated by a tumor of the size of an orange, about the pedicle of which could be felt the neck of the uterus. The finger passed into the os and about the tumor without difficulty. Every examination was followed by severe hæmorrhage. The pedicle was cut through by means of the wire écraseur, and the tumor removed by means of a polypus forceps. Considerable hæmorrhage followed its removal. As this was not controlled by applications of hot water, a tampon saturated with a solution of subsulphate of iron was introduced. This was renewed on the second day. On the fourth her temperature ran up to 103°, she had a chill, and pains in various parts of her body. These symptoms vanished under the use of quinine, digitalis, and opium. Five weeks after the operation she appeared much improved, had had no bleeding, her appetite and strength were greatly increased, the uterus was normal in size, the cervix was still dilatable and would admit the finger with pressure, and the cervical membrane was in good condition. The tumor was of the size of an orange. The mucous membrane of the lower surface was ulcerated, so that vessels were ruptured, allowing hæmorrhage on any exertion. The case was of interest from the long continuance of the hæmorrhage, and illustrated the importance of early and careful examination of the cavity of the uterus in cases of protracted hæmorrhage.

Dr. Goodell seldom used the wire now for the removal of uterine polypi. He preferred traction with twisting or enucleation by the finger. There was less bleeding, and he was afraid of "cupping" of the fundus uteri and its injury by being included in the wire loop. He had made traction with the obstetric forceps, and enucleated tumors so large as to rupture the perinæum even after lateral incisions had been made in the labia. He had partially inverted the womb, enucleated the tumor, and then restored the organ to its proper form. The tumor sometimes occluded the os, and fœtid pus from necrosis of the growth was imprisoned above it, giving rise to a suspicion of cancer.

The President thought Monsel's solution might have caused the high temperature. Vinegar would have been a better hæmostatic, and it was also an antiseptic. From the appearance of the specimen a portion of the adventitious growth seemed to have been left behind, and it would be interesting to know the history of the stump.

Dr. Parish had removed many fibroids of various sizes, and sometimes with degenerated tissues and noisome odors. The rapid recovery of Dr. Montgomery's patient was remarkable. It was much to be regretted when any portion of the tumor was left, as necrotic change was rapid and decided in such tissue, and there was danger of blood-poisoning. The pedicle, however, generally shrank and disappeared.

Dr. Goodell remarked that this tumor appeared to be sessile, and had been wholly removed. The pedicle proper was usually simply mucous membrane, without adventitious tissue, and it made very little difference if some of it was left behind, as it shriveled away and was absorbed.

Dr. Allen had sometimes regretted that he was compelled to leave a portion of pedicle or tumor in the uterus, but he had never seen any bad consequences follow it. He preferred vinegar to iron as a hæmostatic, and considered it as good an antiseptic as carbolic acid.

Dr. Montgomery remarked that the wire had evidently brought away all the tumor. There was no evidence of any remnant on examination to-day. In one case a portion of tumor or pedicle had been unavoidably left, and he had removed it some time afterward by means of a tenaculum. He wounded his finger in doing so, and suffered from septicæmia. The woman had an attack of cellulitis.

Miscellany.

The International Medical Congress.—In its September issue, published before the recent meeting of the committee in New York, the "American Practitioner," of Louisville, says:

"When the handful of agitators who made all the commotion and din at New Orleans in May meets in New York, on the third of this month, they will assume a very different tone from that they used at Chicago in June. Much of their zeal will have been quenched. The wet blanket which public opinion has wrapped about them will have cooled their enthusiasm, while the almost universal condemnation of their movements, both at home and abroad, has demoralized the leaders of the ill-timed and ill-starred revolution and reduced their followers to a mere corporal's guard.

"To speak without mincing words, failure was written all over the new committee from the very start, and it already totters to its fall. Even though it were vouchsafed the wisdom to undo all it did at Chi-

cago, the public mind has been so exasperated by its behavior that nothing short of an unconditional surrender would now be entertained. The feeling of the profession demands this, nor will it accept less. Let the agitators make no mistake on this point. They must lay down their arms and submit, with what grace they can, to be marched to the rear. Nothing short of this will be received as a settlement. This, and this alone, will open the only road that will lead to an International Congress in 1887.

"The National Association made an egregious blunder when it appointed at New Orleans a new committee. It blundered again in the selection of the men who composed the committee. And the committee, true to its origin and its instincts, has blundered from that day to this. Conceived in error, all its steps have been marked by unwisdom and stained by selfishness. Fortunately for the best interests of the profession, not only in this country but throughout the world, its mischievous career is fast drawing to a humiliating close. Before these lines are read the committee will have realized that 'consequences are unpitying.'

"The leaders were bold enough when precipitating this deplorable imbroglio, and remained deaf to all reason. Their ears have been made to hear since that time. The voice of the profession has reached them, and not one of them all is so daft but he realizes that an overwhelming majority of the forty thousand physicians in the United States declines to lend countenance or support to the new committee or its schemes. The more thoroughly the committee digests this fact the better will it be all round. For what manner of congress would a congress be without representatives?"

Commenting upon what is known of the action taken in the committee meeting lately held in New York, the "Medical News," of Philadelphia, says:

"Without wishing to prejudge the work of the committee, we can not refrain from giving voice to the regret that will be universally felt that no effort was made at the meeting to harmonize the grave differences which exist in the profession, and that the expressed views of the European members of the Congress were not deemed of sufficient importance to be accorded consideration."

The "Journal of the American Medical Association" publishes an official report, signed by Dr. Shoemaker, of the doings of the enlarged committee at its sessions in Chicago and in New York. The report includes the rules adopted, the first of which reads as follows: "The Congress shall consist of members of the regular profession of medicine, and of such other scieutific men as the Executive Committee of the Congress may see fit to admit, who shall have inscribed their names on the register and shall have taken out their tickets of admission."

The report contains the following statement: "Lists of vice-presidents, secretaries, and councilmen for each section were named by the Committee of Arrangements, but, as it was not practicable to ascertain at once who would accept the places assigned them, or who of those who had been announced in the medical press as declining to accept positions before the present rules and organization had been adopted, as given heretofore, might wish to withdraw such declination, the final adjustment of these offices was referred to the Executive Committee of the Congress, and all correspondence in relation thereto was transferred to the Secretary-General of the Congress."

Editorially, the same journal, after referring to the action taken at the New York session, asks: "May we not hope, therefore, that a spirit of harmony will be fostered, and that all who hold the honor and interests of the profession above all personal considerations will cease to discuss the past, and cordially co-operate in making the International Congress of 1887 an honor to our country and a benefit to the profession of the world?"

The American Gynæcological Society will hold its tenth annual meeting at the Columbian University, in Washington, on Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1885. Among the papers announced to be read are the following: "The Natural Hygiene of Child-bearing Life," by Dr. S. C. Busey, of Washington; "Remarks on the Use of Tarnier's Forceps," by Dr. Ellwood Wilson, of Philadelphia; "Facial Paralysis in the Infant from the Use of the Obstetric Forceps," by Dr. T. Parvin, of Philadelphia; "The Genu-pectoral Posture in the Prolonged Nausea and Vomiting of Pregnancy, with Cases," by Dr. H. F. Campbell, of Augusta, Ga.; "On Two Rare Cases in Abdominal Surgery" (the President's Address), by Dr. W. T. Howard, of Baltimore; "The Care of the Perinæum during Labor," by Dr. T. A. Reamy, of Cincinnati; "Report of a Case of Cæsarean Operation," by Dr. E. W. Jenks, of Detroit; "Puerperal Diphtheria," by Dr. H. J. Garrigues, of New York; "A Modification of Emmet's Cervix Operation in Certain Cases, with a Case," by Dr. R. S. Sutton, of Pittsburgh; "Inflammation of the Parotid Glands after Ovariotomy," by Dr. William Goodell, of Philadelphia: "A Study of an Unusual Type of Puerperal Fever," by Dr. Fordyce Barker, of New York; "Peristalsis of the Genital Tract," by Dr. J. R. Chadwick, of Boston; "Four Cases of Oöphorectomy, with Remarks," by Dr. Joseph Taber Johnson, of Washington. Members of the profession are cordially invited to attend the meeting.

An Important Discovery concerning the Venous Circulation in the Fingers.—Until now the injection of minute venous radicles in a manner calculated to be of practical service has been impossible, chiefly on account of the resistance of the valves. It is true that injections could be make to reach the veins through the arteries, but in that case both arterial and venous vessels were filled with a material of the same color, so that the two were with great difficulty, if at all, to be distinguished from each other. M. Bourceret has recently overcome the difficulty of injecting the veins in a direction contrary to that of the blood-current, and has thus already been able to demonstrate some striking facts. As described by M. Poirier, in a recent issue of the "Progrès médical," M. Bourceret's process is as follows: The part to be injected is kept in a warm bath (from 104° to 113° F.) for five or six hours. A colorless injection is then slowly and steadily thrown into the main artery. It passes into the subcutaneous veins, and the injection is stopped as soon as those veius appear well defined under the skin, and before they are distended. The largest of the superficial veins is then punctured with a trocar, and the cannula is left in place. Through this, and the cannula which has been left in the artery, both vessels are now at the same time very gently iujected, in a direction away from the heart, the artery with a red and the vein with a blue liquid. The result is that each injection penetrates to the capillaries, and the part assumes the hue proper to it in life. The reason why this procedure enables the venous injectiou to pass the valves is supposed to be, that the liquid previously injected has either distended the veins sufficiently to make the valves incompetent, or has actually forced them against the sides of the vessels. At all events, there is no doubt that the device is successful, but its practice is said to demand a great deal of skill and patience.

By means of this method of injection the following facts have been learned in regard to the circulation in the fingers: There is a special collateral (functional) circulation in the fingers, quite distinct from that which simply nourishes the tissues. The branches given off by the collateral arteries are so few and so thin that the trunks reach the last phalanx but little reduced in size, and terminate in an arch at about the middle of the palmar aspect of the phalanx. Numerous arterial "bouquets" are given off from the arch, and divide in the pulp of the finger. They have no *venæ comites*. The capillaries show a special disposition in the pulp of the finger which is quite characteristic; an arteriole of comparatively large size is seen to divide suddenly into a "bouquet" of large capillaries (from 0·04 to 0·08 mm. in diameter). These capillaries form glomeruli, and then come together again to form a venule. The glomeruli are found in great abundance at the middle of the palmar aspect of the last phalanx, uuder the upper two thirds of the nail, and at the thenar and hypothenar emineuces. At all these points the ordinary type of nutritive vascularization is found side by side with this special circulation.

The veins of the fingers arise for the most part from the last phalanx; their radicles unite almost at once to form trunks of comparatively large size, which proceed toward the root of the finger, forming a subcutaneous layer which almost covers the dorsal aspect. These veins do not form irregular plexuses, but follow a longitudinal course to the first phalanx, anastomosing freely.

The chief characteristic of this special circulation lies in the great caliber of the vessels in proportion to the nutritive demands of the

first phalanx. M. Bourceret thinks that the object of the arrangement is to supplement the nutritive circulation and to warm the parts, but M. Poirier suggests that it may have something to do with the exquisite sensibility of the localities concerned.

"**The Micrococcus Limbergeri,**" says the "American Practitioner," "has recently been the subject of numerous investigations. In fact, every stranger, soon after his arrival in Germany, attempts to investigate it, and with very various results. Unlike those mentioned above, it is very difficult to isolate. One plan, lately suggested by Prof. O'D. Rossa ('United Ireland,' 1885), seems to be feasible. It consists in isolating the micrococcus, together with its pabulum and a large portion of the adjoining sidewalk, by the judicious application of a few pounds of dynamite. This species is *not* good to eat. Your readers will now be relieved to learn that for the present they will be spared any further remarks upon bacteriology, as the *spiro-gyra barrel-organi* is breeding so freely upon some pieces of Lohengrin, just outside the window, that all other matters must be suspended till the disease has been isolated with a boot-jack and destroyed by a moist heat of 212° F."

Even-handed Justice in Paris.—The "Progrès médical" announces that the pharmaceutical interne Reinchard, the involuntary author of the mistake which lately caused the death of two patients at the *hôpital Saint-Louis*, was arraigned before the correctional tribunal on the 26th of August, charged with homicide by imprudence. He was condemned to three months' imprisonment and fined fifty francs. The Sister who purged one of the patients without authorization, and thus caused his death, has not yet been prosecuted. "It will be remembered," says our contemporary, "that things went differently when it was a question of lay nurses. Singular justice; singular administration!"

The Disposal of Anatomical Material in Paris.—According to the "Progrès médical," the prefect of police has ordered that henceforth the *débris* of cadavers from the dissecting-rooms shall be incinerated in the special apparatus lately established in the *cimetière de l'Est*, or buried in some other Paris cemetery.

A Munificent Bequest.—The same journal says that the Countess of Bose, who died in 1883, bequeathed to the Marburg faculty of Medicine 800,000 marks (about $200,000) for prizes, for defraying the traveling expenses of young physicians, etc.

The Cartwright Lectures.—The "Medical News," of Philadelphia, learns that the next course is to be given by Dr. Osler, of that city.

Papine.—Concerning this preparation, Dr. H. T. Bruce, of Waverly, Ala., says: "I have tested papine; it acts charmingly as an anodyne. One of the patients could not tolerate morphine, owing to the nausea and vomiting it occasioned. In this patient pain was allayed and tranquil sleep produced, and no evil effects followed. I noticed that its effects were quicker than was usual from opium. So far I am much pleased, and deem it an indispensable remedy."

THERAPEUTICAL NOTES.

Nitro-glycerin in the Treatment of Hiccough.—Dr. O. T. Schultz, of Mount Vernon, Indiana ("American Practitioner,"), relates the case of a phthisical patient, fifty-eight years old, who had suffered for nine days with persistent hiccough, which had brought him to a very low condition, and had been only slightly ameliorated at times by various remedies, including galvanization of the phrenic nerves and of the epigastric region, and faradization along the attachment of the diaphragm. As the patient had formerly suffered from angina pectoris, the author reasoned that the hiccough might be due to a similar cause. Accordingly, on the tenth day, he gave one drop of a one-per-cent. solution of nitro-glycerin at 8 o'clock in the morning, and repeated it at 9 o'clock. A moderate degree of bursting headache set in at once, the hiccough became easier and less frequent, and by 9.30 o'clock it had ceased altogether. The use of the drug was continued every two hours. At 2 P. M., after the patient had drank a glass of iced milk, the spasms appeared again, but yielded quickly to a fresh dose. During the afternoon and night there was only an occasional hiccough, but the next day there were two short attacks in the afternoon. The medicine was continued, and an occasional dose was given on the twelfth day, when the hiccough had entirely ceased.

Ficus Doliaria in the Treatment of Miners' Anæmia.—Bouchut ("Paris méd."; "Nouveaux remèdes") describes doliarina as a powder prepared with the juice of the *Ficus doliaria*, a plant indigenous to Brazil, where the *Ankylostoma duodenale* (the parasite which causes miners' anæmia) prevails endemically. The powder contains also aromatics and iron. The dose for an adult is a drachm three times a day. In the case of a patient treated by Bäumler the ingestion of the first few doses was followed by borborygmi with pains in the upper part of the abdomen. The next day there were several loose stools, and the evacuations contained great numbers of the ankylostoma. On account of the patient's general condition, due to phthisis, the treatment soon had to be suspended, but it was afterward resumed with success. Bäumler remarks that doliarina, although slower in its action than male fern, and doubtless less energetic in dislodging the parasite, involves no danger, while the use of male fern demands great care. The juice of the *Ficus doliaria* contains vegetable pepsin, which digests the worms, so that, like papain, it is a worm-consumer (*vermivore*).

Sulphide of Carbon as a Revulsive.—"Nouveaux remèdes" says: Take a piece of cotton of the proper size, sprinkle it lightly with sulphide of carbon, apply it to the skin, and cover it with oiled silk. In fifteen seconds the revulsive action will be observed, as shown by brisk burning. If the application is continued for more than thirty seconds the pain becomes intolerable.

Hydrofluoric Acid as an Antiseptic.—According to the same journal, hydrofluoric acid is one of the most powerful antiseptics, and has been used in tuberculosis, both pulmonary and surgical (wounds and glandular inflammations in tuberculous subjects). As a surgical antiseptic it has yielded interesting results. Commercial hydrofluoric acid should be diluted in the proportion of 1 to 2,000, 1 to 1,000, or 1 to 500. Internally, it may be used by inhalation. The patient is to be placed in a cabinet in which two drachms and a half of the commercial acid, diluted with its own weight of water, in a leaden vessel, are evaporated over a water-bath. The inhalation, which should last at least an hour, is to be repeated every day.

Sulphate of Iron in the Gastric Catarrh of Infants.—When absorbents and tonics fail to correct the acidity, Roth ("Pest. med.-chir. Presse"; "Conseiller méd."; "Rev. des mal. de l'enfance") resorts to sulphate of iron, which acts favorably in a variety of ways. In the first place, it is a disinfectant; under its use, the evacuations are changed in color and lose their offensive odor. Being an astringent, it contracts the turgid mucous membrane and coagulates albuminous matters. In order that these effects may be decided, its use should be continued for several days. The author employs the following formula:

Sulphate of iron		1½ grain;
Mucilage of acacia, Syrup,	each	5 drachms.

A teaspoonful to be given every two hours.

Mercury in the Abortive Treatment of Typhoid Fever.—According to Kalb ("Berl. klin. Woch."; "Gaz. hebd. de méd. et de chir."), mercurial frictions, practiced before the ninth day, produce complete defervescence in a few days. The inner aspect of the thigh is to be chosen, and the frictions should last half an hour. At the same time Kalb gives large quantities of alcohol to counteract the damage to nutrition.

Injections for Fœtid Leucorrhœa.—A contributor to the "Union médicale" gives the following formulæ:

Chlorate of potassium	12 parts;
Wine of opium	10 "
Tar-water	300 "

Add three tablespoonfuls to half a pint of warm water.

Salicylate of sodium	20 parts;
Salicylic acid	1 part;
Tincture of eucalyptus	45 parts;
Wine, or white vinegar	300 "

Add two tablespoonfuls to half a pint of warm water.

Lectures and Addresses.

A CLINICAL LECTURE ON DISEASE OF THE HEART AND LUNGS, WITH SPECIAL REFERENCE TO PHYSICAL DIAGNOSIS.

By STEPHEN S. BURT, M. D.,

PROFESSOR OF PHYSICAL DIAGNOSIS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

While directing our attention more especially to the physical diagnosis of disease of the heart and lungs, we are constantly reminded of the intimate relations that exist between them and the remaining organs of the body. A study of these relations forces upon us the conviction that only by thorough knowledge of disease in general may we hope to arrive at anything like precision in the diagnosis of special subjects.

He is indeed a poor practitioner who allows himself to be so carried away by some absorbing specialty as to lose his interest in the general health of the body. But what shall we say, on the other hand, of the physician who believes physical exploration unnecessary, and goes his way, having prescribed for symptoms only?

To the general practitioner an understanding of the methods of physical diagnosis has now become a necessity, and one that is well recognized. It is expected by his patient and demanded by the profession, so universally, indeed, that some are forced to go through a sort of mummery for its moral effect upon the patient, when in reality there is little if any true perception of what the examination reveals. Fortunately, however, this class is in the minority. There is a desire prevalent in the profession, as shown by the increasing numbers at our clinical schools, to grasp the subject of physical diagnosis, and ere long no doctor will think of prescribing for a cough until he has discovered the cause thereof. No practitioner will mistake a functional for an organic disease of the heart; nor will he make life miserable to a patient just because an organic murmur *has* been found. He will be capable of explaining that life may continue in comparative comfort so long as compensatory hypertrophy lasts. Furthermore, he will be able not only to recognize failing compensation, but also to ward off its fatal effects, perhaps for years, by judicious treatment, and finally he will be less likely to interfere when nature does not call for aid—an achievement perhaps one of the greatest in medicine.

Now, let us turn to the study of diseases of the chest as they are presented, not in books, but at the clinic. It is one thing to learn the symptoms and physical signs of disease, and quite another to recognize them in the patient. Here lies the difference in medical men. Book knowledge is important, but some never get beyond it.

The first patient that it is our privilege to examine gives a good family history. She is thirty years of age, has not had rheumatism, nor any severe illness. She complains chiefly of loss of appetite, headache, and flatulence. Upon exertion and on exposure to cold she has a slight cough. You observe that it is not until the leading question has been asked that she tells of any shortness of breath on exertion. Her symptoms are mainly those of dyspepsia. But those disorders of the digestive tract that receive the name of dyspepsia are not always so innocent as they might seem. Not infrequently a grave kidney lesion may be found lurking in the background, and then again the heart may be at fault. A careful examination has excluded the probability of a kidney complication in this case. We will now investigate the heart. Upon inspection, it is seen that the apical impulse is somewhat to the left and below its normal position. The impulse, on palpation, is found to be slightly increased in force. Percussion does not give a marked increase in the cardiac area. Auscultation, however, reveals a soft, blowing systolic murmur, extending to the left, with the point of maximum intensity in the mitral area. Mitral insufficiency is the lesion, and for this the heart muscles fairly compensate. There is neither œdema nor cyanosis.

This is a very instructive case, illustrating as it does one of the secondary symptoms of heart disease—namely, flatulent dyspepsia. Long before serious engorgement becomes apparent there is this slight alteration in the circulation which results in defective digestion. And, too, a little unusual exertion or some slight exposure of the neck and shoulders produces a dry cough. Besides, if you closely watch these patients you will see that there is dyspnœa, not upon ordinary exertion, so long as it is confined to a plain surface, but during an ascent of a very slight elevation, or on any unusual exercise. As a result also of this, the bright-red color of the lips is seen to change to a much darker hue. I have had just such an instance under observation for the past four years. The patient was treated for simple dyspepsia, with very indifferent results, her heart lesion being unrecognized. But when the real cause of her trouble became known she made rapid improvement. A pill containing a grain each of digitalis, iron, and quinine, in addition to the stomach mixture, with, now and then, medicine for the intestines, comprised most of the treatment. The slight cough, which is provoked by a similar condition in the pulmonary circulation, is prevented by taking only moderate exercise and by keeping the superficial circulation active with sufficient clothing.

There is still another very interesting example of venous congestion resulting from heart disease that occurs to me. A patient who was completely prostrated each month by menorrhagia came for treatment, but her errand was as fruitless as it had been elsewhere until I discovered that she had a stenosis of the mitral orifice. No lesion could be found as a local cause. Concluding, therefore, that the excessive hæmorrhage was due to venous stasis, I put her upon large doses of the infusion of digitalis during that period, and the treatment proved most efficacious.

On the other hand, it is a matter of frequent remark, the number of patients that come firmly convinced they are suffering from an organic disease of the heart, because of the pain and palpitation that often attends dyspepsia. A physi-

cal examination enables the physician to dispel all these fears, while properly directed remedies will remove the cause, quiet the heart, and quell the pain.

Here we have exemplified the interdependence of viscera, and, at the same time, the importance of not attending to one to the neglect of another part of the body.

We now have a patient on whom the ravages of time and disease have set their stamp. It is seen, by pitting on pressure, that his ankles are both œdematous. His face, marked with fine red streaks, is pale, and his lips are slightly cyanotic. The pulse is irregular and small. He tells us that exertion produces shortness of breath, and that upon two occasions he has had hæmoptysis. Thus we have evidence of an increased venous and a diminished arterial pressure. By palpation we find the apex of the heart a little to the left of its normal position, with its impulse fairly strong, while epigastric pulsation is forcible. Upon auscultation there is accentuation of the pulmonary second sound, and just over the apex can be heard a systolic murmur. This murmur is not heard in the back; neither is it carried to the left nor to the right. It is the indication of mitral regurgitation, but there is probably very little regurgitation as compared with the amount of obstruction at this orifice.

Delafield says: "The same lesion frequently produces both stenosis and insufficiency of a valve." And here we have the physical signs that most commonly proclaim this condition.

Such a murmur is much oftener present than the auricular systolic, or so-called mitral presystolic, murmur with this lesion. A feeble mitral systolic murmur, due to a weak ventricle, is also confined to the area of the apex, but that is not the case in hand. Exceptionally, a systolic murmur of the kind we have here gives place temporarily to a presystolic murmur. Obstruction of the mitral orifice produces an accentuation of the pulmonary second sound. This is brought about in two ways—first, by pulmonary engorgement and consequent hypertrophy of the right ventricle, and, second, by the diminution of the aortic second sound from decreased arterial pressure in the general circulation.

When hypertrophy of the left auricle is sufficiently in excess of dilatation to follow up the at first passive flow of blood by a firm contraction, in the completion of auricular systole, we may observe the so-called mitral presystolic murmur. But under other conditions of stenosis, unless the valve is closed during ventricular systole, such a systolic murmur will be produced as we find here. The case is of further interest in that we are able to restore the arterial circulation, sufficiently at least to do away with the dropsy. In order to accomplish this we must increase the quality of his blood by food, rest, and tonic medicines. By the addition of digitalis, compensation will be re-established, and thus nature assisted by a timely and not unintelligent interference.

The history and symptoms of patient number three are of a cough, attended at one time by white frothy sputa, at another by muco-purulent expectoration. This began with an hæmoptysis early in the spring. She has night sweats, and believes she is losing flesh and strength. A brother and a sister died of consumption. We are led naturally to suspect incipient phthisis; but the diagnosis of the early part of the first stage, by physical signs, is not always an easy matter; and it is quite beyond the reach of one who has not given some special attention to the subject. We know that fremitus is more marked at the right apex in health than at the left, that the pitch is higher on percussion, that expiration is higher in pitch and longer in duration upon auscultation, and also that vocal resonance is exaggerated. With these signs at the left apex we should be almost certain of phthisis. How, then, are we to determine whether there is phthisis upon the right side? In the first place, the disparity seems to be greater than is found ordinarily in health; and, secondly, there is evidence of a circumscribed bronchitis, shown by the localized subcrepitant râles. Besides, there are a few crackling and crepitant râles, indicating some slight co-existing pleurisy and pneumonia.

These adventitious signs are confirmatory evidence, and, taken in connection with an elevation of temperature, complete the diagnosis.

The advantage of detecting the presence of phthisis at an early stage is very great, for that is the time in which judicious treatment is productive of the best results. While, unfortunately, the greater number do not, still it is a well-established fact that patients do recover from phthisis. We find this demonstrated in autopsies, when death has taken place from other causes, by the presence of cicatrices or encapsulated cretaceous remains of old phthisis. It is also within the experience of many of us to have watched the progress toward recovery. Localized pneumonia undergoes resolution, circumscribed bronchitis disappears, and with them all decisive evidence of pulmonary phthisis.

The next patient comes with a history of a cough which has lasted nearly two years, associated with night sweats, loss of flesh and strength, but no hæmoptysis. His father and a brother died of what he thinks was consumption. Upon inspection, we see that he is much emaciated, especially about the chest. Under both clavicles there is depression, the retraction being more marked upon the right side. On palpation, we find fremitus exaggerated upon the right side, and his respirations are twenty-four a minute. Light percussion shows dullness in the upper part of the right infra-clavicular region and over the upper half of the left side of the chest, while forcible percussion brings out cracked-pot resonance from the left infra-clavicular region. Auscultation reveals bronchial breathing and bronchophony over the right, with amphoric respiration and whispering pectoriloquy in front upon the left side, while behind on the left side are large and small bubbling râles. Thus we have an example of the beginning of pulmonary phthisis at the same time with one approaching its end. It is but ill-conceived advice that sends a patient with lungs in this advanced stage of destruction from home and friends, to find discomfort and finally death among strangers in a strange land; and it would seem that a knowledge of the physical signs of disease should enable physicians to avoid doing this thing.

There are a few cases, to be sure, where phthisis advances to the stage of excavation and remains stationary, the patient practically recovering, but this is rather exceptional. If the physician can decide that the phthisis is non-progressive, and finds the pulse good and the general condition of his patient fair, he may give a guarded favorable prognosis, and possibly allow him to try a change of scene and climate.

To return, then, to our opening proposition, we see in all these cases that a comprehensive knowledge of disease is quite indispensable to a specific understanding of the malady under which each patient labors. And without physical exploration there is no certainty, for different diseases have so many symptoms in common that dependence upon symptoms alone is often misleading. By a thorough examination of each case the physician exhausts all possible causes of any given complaint. He begins to know definitely the matter in hand. He knows what is not as well as what is before him. He can direct his remedies to the true seat of the disorder, and he is not under the necessity of trying what may prove an ill-judged experiment, while without this examination his diagnosis is more or less guess-work. He may be right, for a guess has always one chance of being right; but he will often be wrong, and wrong, too, from avoidable causes.

I can not, therefore, urge upon the student too forcibly the importance of a thorough familiarity with physical diagnosis. He will not fail to be convinced of its supreme value in all cases of thoracic disease.

PHYSIOLOGICAL, PATHOLOGICAL, AND CLINICAL NOTES ON HYDROCHLORATE OF COCAINE, WITH SPECIAL REFERENCE TO ITS USE IN MELANCHOLIA. A PRELIMINARY STUDY.*

By JEROME K. BAUDUY, M. D., LL. D.,
PROFESSOR OF PSYCHOLOGICAL MEDICINE AND DISEASES OF THE NERVOUS SYSTEM, MISSOURI MEDICAL COLLEGE; SENIOR ATTENDING PHYSICIAN TO ST. VINCENT'S INSTITUTION FOR THE INSANE, ST. LOUIS.

This remedy is one of the great discoveries of the present century. Notwithstanding its recent triumphs in ophthalmological fields, I believe it will have its greatest future in the treatment of many forms of obstinate nervous disease. Anæmia, depression, prostration, neurasthenia, and particularly many disturbances of the vaso-motor system, will be the domain of its most brilliant therapeutical achievements. Having experimented extensively and perseveringly with this wonderful drug, I feel it incumbent upon me to lay before the profession the conclusions I have reached, although many of them are still not sufficiently matured by time and experience.

My attention to the internal use of the drug was first awakened early in January of the present year by reading an able article by a German physician, Dr. Fleischl, of Vienna, detailing the results he had obtained in the treatment of alcoholism and morphinism, in which he enthusiastically maintained that inebriate asylums were a thing of the past.

I shall consider the drug in relation to its effects on all the more important organs.

The Stomach.—After the exhibition of a dose of cocaine to one unaccustomed to it, intense and persistent nausea generally manifests itself. So certainly is this a fact that it is necessary to administer it several hours before a meal is taken; otherwise the anorexia which follows, along with the nausea, will prevent the taking of nourishment. This fact is to be especially remembered in the treatment of melancholia, in which (so far as can be learned) I was the first to suggest its use. If this is not remembered, it will, of course, greatly militate against the result to be attained, since systematic feeding holds an important place in the treatment of this condition.

One of the most striking and, at the same time, interesting effects of cocaine upon this organ, from a therapeutic standpoint, is that *vomiting is not possible*, however intense the nausea may be. This is due either to a paralysis of the gastric motor-nerve supply, which seems to be almost *sui generis*, or to a selective anæsthetic effect. Although the appetite is abolished, there is no interference with the digestion of food taken, in spite of the anorexia. The following incident led to this discovery:

A patient, to whom cocaine was administered some hours after the ingestion of an excessively large meal, was suddenly seized with violent symptoms of indigestion. As he was in great distress, an ordinary domestic emetic was given; this failing to act, one or two more strong doses of a similar character were administered with no result—such as large doses of salt, mustard, and warm water. They were given until the stomach was distended, with no effect except to add to the patient's distress. Ipecacuanha and alum, in fair doses, likewise proved futile. Everything having failed, and the patient's distress from the emetic agents becoming very great, efforts in this direction were stopped. In due course of time the contents of the stomach were carried off by a profuse diarrhœa, which afforded the first relief the patient experienced.

From this and analogous cases I concluded that cocaine should be ranked among the most efficient of anti-emetic remedies. For this I also claim priority, for, early in January, 1885, I suggested to my friend, the late Dr. P. V. Schenck, to make trial of it in cases of the obstinate vomiting of pregnancy. He soon reported before the Medico-Chirurgical Society of St. Louis most complete and brilliant success in two cases in which all ordinary remedies had failed. He was enthusiastic on the subject, and warmly urged me to publish my results. His early death, unfortunately, prevented further experiments in this direction, as I myself have not treated cases of this character for many years.

I have already referred to the loss of appetite which the drug produces. The anorexia is the most certain and complete I have ever witnessed as resulting from the use of any drug.

* Read before the American Neurological Association, June 17, 1885.

In cases of the ordinarily uncontrollable vomiting of hysteria, as well as in all cases in which it is desirable to administer nauseating drugs to patients presenting gastric irritability—ipecacuanha in dysentery, for example—I am convinced that cocaine will prove very useful.

Genito-urinary System.—Although I have made no chemical or microscopical investigation of the urine as modified by the use of cocaine, the time at my disposal having been too limited, I believe that the urinary organs offer an extensive field for observation. It is certain that it produces a largely increased flow of urine, and, as a result of its abuse, a slightly paralytic condition of the bladder. The patient finds it difficult to begin the act of micturition, and, when the act should have been finished, the urine continues to dribble away for some time, as in the incontinence observed after overdistension from retention. From this fact it has occurred to me that it would be well to try the remedy in cases of irritable bladder, whether due to cystitis or to perverted nervous and muscular action, a condition which so frequently baffles the best efforts of the physician.

Upon the sexual organs cocaine acts as a direct stimulant. Among aphrodisiacs I have found it the only reliable agent. In this as well as in other regards it proves directly antagonistic to morphine, which, as is well known, is a powerful anaphrodisiac. The most remarkable results may be effected by bringing the system under the conjoined influence of the two drugs. Veritably atrocious teasing effects are thus induced; the individual will be swayed by the stimulation of his desires to violent and frequently repeated sexual efforts which will almost invariably prove futile or be held in abeyance by the restraining influence of the morphine. The tortures of Tantalus will be repeated, the punishment being transferred to the sexual appetite, which can not be gratified, and being, if anything, more acute than that caused by excitations of thirst and hunger.

A singular effect of the drug is sometimes to be observed in the act of coition. There seems to be present a state of erethism, making it difficult for the individual to determine precisely when the orgasm has been begun or completed. This singular state of affairs is, in some instances, so pronounced as to perplex the individual as to the time when withdrawal should be accomplished. The condition is probably due to a morbid irritability resulting in a disturbance of the reflexes.

Circulatory System and Respiration.—The heart's action is increased both in strength and in frequency under the influence of medicinal doses of cocaine. This is confirmatory of the effects observed by South American travelers from chewing the leaves of the plant. When the dose is excessive, or its use too long continued, the pulse becomes weak and still more frequent, and dyspnœa follows slight muscular effort. The respirations are always increased in frequency to correspond with the acceleration of the heart's action.

The Vaso-motor Nervous System.—It is probable that many of the phenomena already described are due to the effect of the drug upon the nervous apparatus of the arterioles and capillaries, but I desire to lay some stress upon certain effects of this character not alluded to before. Immediately after the hypodermic injection of a full dose of cocaine the capillaries of the skin become contracted. If there has been any flushed condition of the face, it is immediately replaced by very pronounced pallor. The mouth and throat become dry—at least subjectively—the pupils dilate, and profuse diaphoresis usually occurs, if the dose is large and repeated.

In these results there is a strong resemblance to the action of pilocarpine, and at the same time a very remarkable dissimilarity, all therapeutically in favor of cocaine.

Jaborandi and its alkaloid produce nausea, but also vomiting; they cause diaphoresis, but at the same time salivation; they depress the action of the heart, sometimes to an alarming degree, the reverse of the ordinary effects of cocaine. Not quite so certain nor so persistent in its effects upon the secretions of the skin as pilocarpine, it is far more agreeable and safe in its action in cases of cardiac dropsy.

The Cerebro-spinal Nervous System.—The reflexes are all exaggerated. This is peculiarly shown in the act of defecation. It should be observed that, in consequence of the increased secretion of the skin and kidneys, the alvine evacuations become dry, hard, and infrequent. When there is an attempt made to relieve the bowels, the act is accompanied by spasmodic contractions of the abdominal muscles, efforts simulating the throes of the parturient female; the hardened fæces are expelled with force, and every muscle in the body seems to partake of the spasmodic action. There is thus danger of laceration of the sphincter ani, formation of fissure of the anus, aggravation of hæmorrhoids, and, in persons of advanced age whose arteries are degenerated, cerebral hæmorrhage, as a consequence of these violent expulsive efforts.

As soon as a medicinal dose of cocaine has reached the general circulation, a feeling of well-being is experienced; all sense of physical or mental fatigue which may have been present disappears as if by magic; the mind becomes excessively clear; ideas constantly flow, and the faculty of speech seems especially exalted. In fact, it would thus appear that the island of Reil and adjacent speech centers felt especially the force of the drug. So long as these effects are continued, sleep is impossible; no fatigue is experienced from continued muscular movements, no matter how prolonged.

These effects upon the cerebrum give the key to its employment as a therapeutic agent.

Therapeutic Effects.—It has been well known for some time that the fluid extract of coca was a valuable remedy in the treatment of alcoholism and the opium habit, but it is not to be compared with the alkaloid cocaine in this regard. For a remedy of uncertain strength and action we have in cocaine one whose effects can be predicted with mathematical certainty. It not only replaces alcohol and morphine, but it generates a positive disgust for these agents. They can be withdrawn completely and at once without the slightest suffering or injury, and the cocaine itself may be gradually dispensed with, thus eventuating in perfect recovery.

The only caution to be observed in these cases is *to administer the drug hypodermically, and this by the hand of*

the physician himself. This I particularly insist upon. The drug should not be known to the patient, nor the amount of the alkaloid which is being given. If these precautions are not adopted there is great danger—nay, a certainty—that a *cocaine habit* will be formed, more disastrous in its results than alcoholism or morphinism.

I have already referred to its uses in the obstinate vomiting of pregnancy and of hysteria, and would only add in this relation that there is nothing which relieves any of the ordinary manifestations of hysteria so rapidly and completely as a hypodermic injection of cocaine. The same effects may be expected from its use in cerebral and spinal anæmia, "spinal irritation," neurasthenia, and, in general, in all those cases where the brain and spinal cord do not properly perform their functions from want of proper blood-supply; in all these I believe cocaine will prove the remedy *par excellence.*

I have tested its powers in the cold stage of intermittent fever, and have secured the happiest results. There is a return at once of a feeling of warmth, and the skin begins to act, thus bridging over both the cold and the hot stage of the fever. In pernicious cases I have no doubt it would prove of the greatest value. Indeed, as the temperature is increased, both subjectively and objectively, at least 1° F., I have great expectations of its value in the algid stage of even such a disease as cholera.

In chorea gravior, in convalescence from protracted illness of any kind, in blood-poisoning—in fine, in all cases where there is excessive tissue metamorphosis without corresponding constructive changes—I believe cocaine to be a most valuable remedy.

Insanity, however, I believe furnishes the great therapeutic field for the useful administration of cocaine. Especially is this true of melancholia and hysterical and hypochondriacal insanity; in these especially there is a great future before it.

The records of all asylums will show that melancholia is usually a long-continued and tedious disease to treat—one which most alienists naturally dread to encounter. The rapid relief and satisfactory therapeutical results which are observed in mania so frequently, the shortening of its duration, and the control of its more prominent manifestations, are not observed in the treatment of melancholia. Protracted mental depression with accompanying physical prostration are the constant conditions present. Anything which will alleviate this condition and shorten its duration is a boon to suffering humanity. I therefore urge upon the profession to fairly, extensively, and perseveringly test this drug and verify or disprove the wonderful results I profess to have secured in this direction. These effects are so wonderful that they must be witnessed in order to be believed.

As yet I have not had so much time as is desirable to fully experiment with this remedy, but my results obtained at St. Vincent's Institution during the past six weeks have been in every case eminently satisfactory. In certain cases, only to be ascertained by experiment with the drug, it certainly appears to act as a specific. In most cases of melancholia, even those of very long standing, its effects are manifested almost instantly after giving it hypodermically. My usual method has been to inject one grain, dissolved in ten minims of distilled water. Making all allowance for idiosyncrasies, differences in individuals, variations in the purity of the drug, and other factors not necessary to mention, it may be said that within five minutes the specific effects are fully manifested. The patient who has been morose, silent, taciturn, a prey to the most profound grief or sadness, recovers his normal self, begins to talk about his case, and wonders how he could ever have experienced such gloomy ideas. The cloud over the mind is dispelled, and, instead of the anorexia felt by the normal individual who takes the same dose experimentally, the melancholiac no longer refuses food, and, in place of inveterate insomnia, will have a good night's rest. It is in recent cases that its curative effects are most manifest. In those of prolonged standing these results are apt to be rather transitory. In one case, that of a suicidal melancholiac from Arkansas, recently admitted into St. Vincent's Asylum with an ugly gash in his throat, the duration of the disease was less than a month from the time of his arrival at the institution. Only five injections of cocaine were given, and he was discharged, completely restored to mental health, before his injury about the throat had completely cicatrized.

About fifteen patients are yet under treatment, some of whom are greatly improved, some almost convalescent, while a few have received very little permanent benefit from its administration.

A very intelligent young man (still my patient) has written a graphic description of the effects of the cocaine treatment upon his melancholia, for which he alleges the best results, even declaring that it has induced an abolition of his suicidal tendencies. This letter I shall be happy to read to any of the gentlemen present who so desire. In chronic cases the effects are to produce a "lucid interval" which may continue from one to twenty hours. It is too much to expect that permanent good results can be effected in such cases from any course of treatment whatsoever.

Toxic Effects.—Too frequently repeated medicinal doses or very large quantities of the drug, injected subcutaneously at once, produce results alarming both to the subject and to the spectators. The entire surface becomes pale and covered with perspiration; the pupils dilate gradually and are insensible to light; profound nausea, but no vomiting, follows; the muscles of mastication become more or less rigid and affected with clonic contractions, this effect being produced only among the earlier physiological and toxic effects; there are violent grating and gnashing of the teeth, so that small portions of the enamel are ground off. Tonic contractions of the same muscles (trismus) are sometimes observed, but exceptionally. The eyes assume a fixed, wild, staring gaze that is as characteristic as it is indescribable. There is ceaseless jactitation, with a sensation of wild nervousness that is almost unbearable. There is voluminous loquacity, an extraordinary fluency of speech, the volubility of which must be witnessed to be credited. Excitations of the sexual propensities, one rapidly succeeding the other with astonishing celerity, of a teasing character, are generally observed. Superadd to these phenomena visual and

auditory hallucinations and illusions of the most painful character, and you have a conception of the clinical characteristics of acute cocainism. I do not know the lethal dose of cocaine. If given in sufficient quantity, it would doubtless induce epileptiform convulsions, terminating in death from exhaustion.

Chronic cocainism, or the cocaine habit, presents in an exaggerated form most of the phenomena just described, and some additional ones worthy of record. One case has come under my observation which I will give *in extenso*:

In February last a retired druggist was committed to my charge. He had for many years been a hopeless victim to the morphine habit. The morphine was suddenly withdrawn and hypodermic injections of from a grain to a grain and a half of cocaine, twice daily, were substituted. The result was brilliant and marvelously rapid. The craving for morphine immediately ceased, and all the distressing phenomena usually following the sudden cessation of the use of the drug failed to manifest themselves. Cocaine answered every purpose as a nervous stimulant. But I was somewhat alarmed at ascertaining that a corresponding demand for cocaine was rapidly developing itself—that *a cocaine habit*, the literature of which is as yet a blank, was being formed. Alarmed and dreading the responsibility of subjecting him to unknown and, probably, pernicious influences, I sought immediately to diminish the doses he was taking. Against this, however, he rebelled, and my protests and arguments failed to withdraw him from the rapid formation of a habit apparently more alarming in its results than the terrible slavery entailed upon him by his former habit. My consent to the further administration of cocaine was therefore withdrawn. At that time all craving for morphine and all necessity for its use had disappeared.

Owing to his former occupation, he had no difficulty in procuring the drug in large quantities and taking it by the subcutaneous method. His familiarity with drugs made him all the more reckless, and he daily became more and more enthralled. He often took from twenty to thirty grains daily. He has frequently endeavored to shake off the habit, but he finds this impossible. It is vastly more powerful and fascinating than his previous tyrannical master. I have frequently prescribed the free and narcotic use of morphine as an antidote, but this he has refused to use, seeming to entertain a veritable disgust for the agent which had formerly exercised such a power over all his life and actions.

About this time he sustained a severe concussion of the spine, and came under my daily observation, so that I have had ample opportunities for observing and studying the effects of the constant use of this powerful alkaloid in full doses.

The teeth also are implicated in the ravages of this drug, decay and absorption of the roots occurring.

The effects of its internal use upon the eyes have not, so far I know, been thoroughly studied, but I am convinced that the sight becomes enfeebled—a tendency to amblyopia—which is more intensified in the later stages of chronic cocainism. I have also observed diminution of the sense of hearing. Visual hallucinations and illusions, depending upon cerebral disturbances, and, of course, not upon ophthalmic factors, will be referred to subsequently.

The appetite is completely abolished, and, while there is a subjective sensation of dryness of the mouth and fauces, they are found moist on inspection. For weeks—nay, for months—during the continuous administration of the drug and impregnation of the system by it, all desire for food ceases, and I am satisfied that inanition would ensue were not the will-power exercised or forced feeding accomplished. Although very little nourishment is taken, the body does not emaciate to any such extent as under ordinary circumstances of deprivation. There must be some nervous impression or stimulation produced which greatly compensates for the want of physiological nutrition. This is probably due to a lessening of tissue metamorphosis to a minimum.

As regards sleep, the effects are as extraordinary as they are certain. Insomnia is the rule—an insomnia which is not followed, commonly speaking, by the exhaustion ordinarily thus produced. It is astonishing how night after night, during which sleep is almost entirely unknown, are succeeded by days during which the subject is not apparently greatly depressed, not unrefreshed, during which he is able—not, however, without effort and procrastination that are characteristic, increasing—to resume his daily labors, and even perform brain-work of considerable complexity. In fact, I have seen this insomnia kept up for three and four consecutive days and nights, and yet no very marked injury could be observed as a consequence. The nights are sleepless, yet so great is the fascination of the drug that the patient prefers his insomnia to his accustomed rest, although aware that the most arduous duties await him in the morning. This, to my mind, is an all-conclusive proof of the dangerous power and terrible slavery to which this alkaloid subjects its hapless victims.

Nausea and excitations of the sexual functions, already alluded to, add to the patient's distress; but these he bears, overpowered by a fascination which can not be resisted. He experiences the paradoxical delights of "enjoyable suffering."

Visual and auditory hallucinations and illusions of a very painful character make him fear that at every pass he will encounter some dread object. These cocaine effects will make cowards of the bravest men, causing them to arm themselves heavily to guard against the ever-anticipated dread encounter. When the dark vistas and oppressive silence of night arrive he excludes the pure air of heaven, however overheated the room may be, and he blocks up the very key-holes of his doors to exclude unknown and unreal dangers.

In concluding a study of the phenomena produced by the poisonous effects of this drug, I may say that the most alarming are: the most debasing enslavement of the will, a general demoralization which is as diabolical as it is indescribable, and which tends rapidly toward depravity and to the development of everything that is degrading and ignoble in human nature. The influence of alcohol and of other alkaloids and narcotics, so well known and so frequently described, pale into insignificance when compared with that of cocaine. Habits of the most detestable character; a settled indifference to every interest of life; destruction of the most noble affections and affiliations; the utter death of friendship and of all the nobler qualities; complete disregard of all social and domestic duties, of even pressing family necessities and the common interests

of daily life; the radical extinction of every previous religious spark that has enlivened the soul; the development of the most intense selfishness—these are the certain results of indulgence in this the most powerful and devilish drug which it has ever been the misfortune of man to abuse. The most powerful morphine habit of which we can conceive is to the power and bondage of cocaine as the weakest sapling to the full-grown oak.

Note.—A case has just been reported to me by Dr. A. B. Nichols, of this city, in which he used one quarter of a grain of hydrochlorate cocaine internally for vomiting in a woman advanced seven months in pregnancy. The vomiting was arrested by the first dose administered.

ON THE USE OF COCAINE IN MINOR SURGERY.*

By HENRY TUTHILL HALLECK, M. D.,
BROOKLYN.

Considerable has been written and said during the last few months, in the journals and elsewhere, relating to the use of this new drug. Its use in medicine is of recent origin, as it has only been known to the profession since October last.

As time passes, however, this drug seems to be gaining a firmer foothold in therapeutics, and its field of usefulness is constantly widening the better it becomes known. Almost every day we hear of some new application to which this new remedy has been put, and in which it has been found decidedly useful.

The only drawback to a more extensive use of the remedy is the very high price at which it is sold; weight for weight, it is considerably more expensive than 18-carat gold.†

Since its discovery, or rather its application to medicine, in October last, it has been used by a large number of physicians in one or more cases both in surgical and in medical practice.

I have used the drug in two cases in minor surgical operations. The most important evidence in its favor, however, is based upon notes obtained from the surgical practice of Dr. George Wackerhagen, of this city.

Case I.—This was that of an adult forty-five years of age, and a case of phimosis. The operation was done under somewhat peculiar circumstances, as it was not in reality a necessary one. The patient had recently had his two sons operated upon, and partly for that reason and partly because he was a man of some scientific acquirements and was anxious to test the efficacy of cocaine, he was desirous of having the operation performed—so much so that he told the doctor if he would not perform it he would get some one who would. Under these circumstances Dr. Wackerhagen consented. As the patient was determined to be a martyr to science, the doctor would not deter him. A four-per-cent. solution of the hydrochlorate of cocaine was introduced hypodermically at the dorsal base of the penis, on either side, simultaneously painting the prepuce thoroughly, two or three times, over the point where the incision was to be made, after which he waited for fifteen minutes to get the desired effect. At the expiration of this period there was still some tenderness of the foreskin, when the forceps was applied for the purpose of extension. Five minims more were introduced hypodermically. Soon the penis became numb, cold, and blue. Five minutes later the doctor commenced the operation, using a clamp after the usual custom in operating for phimosis. This patient did not have the slightest pain at any time during the operation, according to his own statements. He said, further, that he would not have known that the operation was being performed if he had not been looking at it.

Case II.—Another adult, twenty-eight years of age. This was a case of stricture of the urethra. Dr. Wackerhagen commenced the operation by introducing 30 minims of the hydrochlorate of cocaine with a urethral syringe, afterward closing the meatus and holding it so as to prevent any escape. Then he injected 10 minims into the tissues at the dorsal base of the penis. After waiting a sufficient length of timef or the anæsthetic to take effect, he introduced the urethrotome and cut up to No. 37, French measure, the patient having no pain. He then introduced a bougie, and found the stricture had not been fully divided. The urethrotome was reintroduced and the stricture cut to 40, watching carefully at the same time for any symptom of pain that should manifest itself. At this cutting the patient did complain of some pain, but said it was very slight. So little pain did he experience, according to his own statement, that he would not think of taking ether were the operation to be performed again.

Case III.—This was another case of urethral stricture in the male adult. It was very similar to the last, but here no hypodermic of cocaine was used. Thirty minims (ten minims three times, ten minutes apart) of a four-per-cent. solution of hydrochlorate of cocaine were introduced into the urethra and retained for a sufficient length of time to produce anæsthesia, after which the urethrotome was introduced and the canal cut to No. 40 in the French scale. The urethra was cut from three inches and a half back of the meatus to the corona. This man manifested no symptoms of pain during the operation.

Another marked feature from the use of this drug was that no chill was experienced in any of the foregoing cases, and in all, especially in the operation for phimosis, its marked hæmostatic action was readily apparent.

Case IV.—This patient was also an adult, but with an ulcer of the rectum. He was a man of forty-two years. The anæsthesia in this case, however, was a failure, the effect was nil, and the patient complained of pain all through the operation. The mucous membrane of the rectum was painted with a four-per-cent. solution as high up as could be reached. No hypodermic was employed. After waiting for twenty minutes for the anæsthetic to take effect, the operation was commenced. The patient complained that he felt the pain just as keenly as if nothing had been used. The non-success of the drug in this case was attributed to two causes: first, that the preparation used was of American manufacture, whereas in all the former cases the foreign make had been used; secondly, to the much greater difficulty of properly applying the drug to the mucous membrane on account of the locality. The doctor finished the operation while the patient uttered maledictions on the drug.

Dr. Wackerhagen remarked that he preferred not to use it in the case of children, for the reason that it would be impossible to keep them still enough to operate with any degree of satisfaction, even when absolutely no pain was produced.

Case V.—This was the case of a man, thirty-two years of age, affected with urethral spasm, who was taken to New York to see Dr. Fessenden N. Otis. He also had a stricture. Dr. Wackerhagen demonstrated to Dr. Otis that a No. 7 sound was

* Read before the Brooklyn Pathological Society, March 12, 1885.

† Since this was written the price has declined, so that Squibb sells it at 18 cents a grain.

firmly held in the urethra by the spasm. After removing the No. 7 sound, however, and injecting about thirty minims of the hydrochlorate of cocaine and waiting for an appropriate length of time, a No. 28 sound would slip out and in easily. Several other New York surgeons were present and witnessed the operation, which was eminently successful in two ways: first, by proving that the drug could relax spasm, and, secondly, that there are sometimes strictures with spasmodic complications.

For notes of the two following cases I am indebted to the kindness of my friend, Dr. A. H. P. Leuf:

Case VI.—This patient was a young man with an old sebaceous cyst, located over the middle of the right sterno-mastoid muscle. The offending body was inflamed and pointing, and surrounded by a wall of inflammatory new formation about half an inch thick. The skin was repeatedly painted with a four-per-cent. solution of the hydrochlorate of cocaine for some time before operating. Five minims were injected hypodermically on either side of the sac. The anæsthesia produced here was so very superficial and unsatisfactory that the operation was concluded under ether. It is possible that a stronger solution might have been used with a better result.

Case VII.—This was the case of a young English surgeon, from whose tarsal cartilage Dr. Leuf removed a small tumor. This tumor was of about the size of a pea. The cutaneous surface of the upper eyelid was thoroughly painted with the solution, by means of a small brush, several times before the operation was commenced. The incision was made and the cocaine was continually applied, waiting by spells for the anæsthetic to take effect. He proceeded very slowly with the operation, which he was compelled to do in consequence of these interruptions, and, after all the care that was exercised in this case, much pain was evinced, and the anæsthesia was very unsatisfactory. Dr. Leuf stated that under the influence of ether the operation ought not to have taken more than five minutes, whereas with the cocaine it took nearly an hour, the pain being felt almost as acutely as if no anæsthetic had been used. No hypodermic injection could be given on account of the locality.

The next and last two cases which I shall relate occurred in my own private practice. These were more satisfactory than those in which Dr. Leuf used the drug.

Case VIII was that of a youth nineteen years of age. The operation was for phimosis. The foreskin was not so tightly contracted but that the mucous membrane could be easily reached with a fine camel's-hair brush and painted, which I did very thoroughly with a four-per-cent. solution of the hydrochlorate of cocaine (Merck's). This was repeated several times, and I waited for fully half an hour before operating, painting the foreskin, both on the mucous membrane and on the cutaneous surface, at very short intervals during the whole half-hour. I did not use any hypodermic injection in this case. I had given the patient his choice before the operation whether he would take ether or would have the cocaine, and he preferred the latter. The pain he experienced was extremely slight during the cutting part of the operation, the sutures causing somewhat more, but not enough to give rise to any very serious discomfort. He said he greatly preferred it to ether, which he had taken on a preceding occasion. The operation performed was that of Professor Wight. I also noticed that the hæmostatic effect in this case was good. The hæmorrhage was far less than in those cases in which I have used ether as the anæsthetic.

Case IX was that of a lady who very much dreaded to go under the influence of ether. The removal of a sebaceous cyst from the scalp was to be the operation. I doubted the efficiency of cocaine very much in this locality; however, I resolved to give it a trial, and, as I could not hope to produce any anæsthesia from its external application, I accordingly injected with my hypodermic needle fourteen minims of Merck's four-per-cent. solution of hydrochlorate of cocaine. Seven minims were injected at the anterior base and seven minims at the posterior base of the tumor. I then waited for twenty-five minutes for the cocaine to take effect. On making the linear incision, the patient felt some pain, and, as the spot was not a particularly sensitive one, I doubted somewhat whether the cocaine had anything to do with relieving the pain. However, on pulling out the sac, I thought that the sensation was very much deadened. She complained of some pain, it is true, but did not make half the fuss I expected.

I have also applied cocaine to the mouth with very good effect in one case. It was that of a child only a few months old. It was teething, and I rubbed the swollen gums with my index-finger, first moistened with the solution of cocaine. The child appeared decidedly easier after a quarter of an hour or so, and ceased crying after having it applied a second time. My experience with cocaine has been fairly satisfactory, and I shall continue to use it whenever I think it practicable.

There seems to be a goodly number of conflicting statements with regard to its efficacy, but whether only apparent or real remains to be demonstrated. It is said by some that the American article is useless, and that the imported one only is of use as an anæsthetic. One strong point in its favor is, that in every case where it will take the place of ether it does not leave the patient sick for hours afterward, as is usual after the use of that anæsthetic.

It would also be an interesting point to learn just how strong a solution could be used with safety to the patient to avoid sloughing, gangrene, etc., which might possibly be the effect if too strong a solution should be used, because of its astringency and possible effect upon the trophic nerves. Its application in medicine is likely to be far more extensive than in surgery, and any method by which its field of usefulness can be extended, whether by experiment or otherwise, is certainly praiseworthy.

THE HOME TREATMENT OF PHTHISIS.*

By F. C. SHATTUCK, M. D.,
BOSTON.

About ten years ago, when making a visit in a French hospital, I heard the epigrammatic professor say to those who accompanied him: "For phthisis, gentlemen, there are but two remedies, opium and lies." Of course he did not mean his statement to be taken in absolute literalness, but the remark affords a good illustration of the view which has been held in the past by the profession and the laity alike, but which is undergoing, and will undergo, further modification. Let me quote what another French professor, M. Jaccoud, says in his work, the English translation of which has just appeared: "To sum up what has been stated, pulmonary phthisis is curable in all its stages. This is the prolific notion which presides over the whole history of the

* Read before the American Climatological Association, May 27, 1885.

disease, and which should uneeasingly inspire and direct all medical action." *

There is very little disagreement among doctors as to the fact that the chances of recovery are much better for patients so situated that they can have a suitable change of elimate, or, at all events, move from the city to the country; but is removal indispensable to cure? The experience of nearly every physician in active practice answers this question more or less conclusively. Dr. Flint has shown that a certain proportion of the phthisical recover not only without climatic, but practically without any treatment; that in some eases phthisis ends by self-limitation. But allow me to dwell for a moment on the vital statistics of my own State. In 1857, 39·50 deaths from consumption occurred in Massachusetts for each ten thousand of the population; in 1883, 29·90, the diminution being gradually progressive during this period, as is seen in the accompanying table which I take from the registration reports. These figures show a still larger decrease in the mortality from consumption among the native population, for the decrease has taken place in spite of the constant influx of foreigners, and notably of the Irish, who are proved, by the studies of the late Dr. T. B. Curtis and others, to be especially prone to this disease.†

Death-rate from Consumption in Massachusetts per Ten Thousand.

1857	39·50	1871	33·93
1858	38·42	1872	36·26
1859	38·85	1873	35·36
1860	37·02	1874	32·80
1861	36·77	1875	34·73
1862	34·28	1876	32·35
1863	37·26	1877	32·93
1864	37·89	1878	32·00
1865	36·79	1879	30·42
1866	35·33	1880	30·81
1867	32·55	1881	31·50
1868	32·20	1882	30·10
1869	32·88	1883	29·90
1870	34·33		

This decrease is altogether too large to credit to greater accuracy in diagnosis and to the transference of consumptives to other States, but is mainly attributable to the prevention of phthisis by improved hygiene, especially among the native-born. Still it seems to me fair to carry some of the improvement to the account of the arrest and cure of actually developed disease through early diagnosis and more rational home treatment, hygienic as well as medicinal.

There are two classes of consumptives for whom the home treatment is the only treatment—those whose means do not allow a change of climate, whatever the condition or stage of their disease, and those whose condition is such that, whatever their means, they had better stay at home and die among their friends, surrounded by the comforts which are to be found in the homes of the well-to-do, but which can so rarely be secured, especially in this country, in hotels or boarding-houses. It is true that some of the latter class, buoyed up by the hopefulness so often characteristic of this disease, will not be said nay, and succeed in finding a physician who counsels a change or else take the matter into their own hands; these do not, however, immediately concern us. Nor does it come within the scope of my paper to discuss the questions as to the rules which are to guide us in selecting cases for which a change of climate is desirable, or in selecting a climate for any particular case. The fact remains that the vast majority of consumptives must, perforce, remain at home. How can we best aid the recovery, prolong the life, and alleviate the sufferings of these patients?

I have no novel or startling views to lay before you, and shall probably not be able to tell you anything which you do not know already. In the discussion which follows the paper, if not in the paper itself, there will be valuable suggestion. What I have to say is, of course, without special reference to the particular climate which may belong to the home of the can't-get-away consumptive.

The consideration of the treatment of phthisis falls naturally into two great divisions, the hygienic and the medicinal; let us take up the more important first, including under hygiene food, morals, fresh air, rest and exercise, dress, and bathing.

Phthisis (or the tubercular bacillus, if you will) resembles one of those weeds which grow only on poor or neglected soil, but it also exhausts completely what measure of virtue the soil may have; hence, by every means at our disposal, we should seek to improve the general health of our patients, that we may aid nature in choking out the disease. The key to the position in the present state of our knowledge is in attention to digestion. A patient of mine, a brilliant example of complete recovery, said to me: "As long as my stomach held out I was not very anxious." Every consumptive should eat the maximum amount of nourishing food which he can digest—which he can digest, let me repeat—for, as Lauder Brunton pithily says, we should always remember that food within the gastro-intestinal tract is still practically outside of the body. There are general laws of dietetics, and we know how long it took the stomach of St. Martin to deal with many different articles of food. Certain materials and certain methods of preparation agree better than others with the majority of mankind; but in dealing with patients we give our advice to individuals, not to men or classes of men collectively. In dietetics, as in a Western mining camp, every man is in large measure a law unto himself. I am often reminded of a wretched child suffering from congenital syphilis and rickets, among other things; the bowels were loose, did not improve readily under treatment which I considered to be suitable, and the weather was characteristic of the season—summer; so I sent the child and its mother to a healthy place in the country, with careful directions as to diet and drugs. After some weeks the mother returned

* "Curability and Treatment of Pulmonary Phthisis," translated by Lubbock, pp. 27 and 28.

† For full details on this latter point, which it is impossible for me here to further develop, I must refer to the very able "Report on the Sanitary Condition of Boston," written by Dr. Curtis in behalf of a medical commission appointed by the city. The report was published by the city in 1875.

with more of a child than she took away, and, on questioning her, I learned that for a time she conscientiously followed my directions, but was not rewarded by seeing any improvement; blueberries were plenty in that part of the country, the child craved them, the mother with misgivings gave them, and the diarrhœa promptly ceased. Our distinguished member, Prof. Flint, says, in writing of dyspepsia, that sufferers "must follow the dictates of instinct rather than any precise rules." I was delighted to find this warrant for the assent which my far more limited experience has led me often to accord to the request of patients, and particularly consumptives, for special articles of food, however bad the reputation of such articles as regards digestibility might be; never in the case of a consumptive have I had reason to regret the indulgence. I think we are perhaps oftener called upon to give minute directions as to the frequency with which food is to be taken than as to the form which it is to assume. Much more work can often be got out of the stomach without remonstrance by five, six, or seven light meals a day than by three heavier ones. A glass of milk or the like, with or without a raw egg, and a little alcoholic stimulant, midway between meals and at bedtime, may be of more service than anything contained in the drug-shops; and a cup of hot bouillon, as soon as possible after waking, will carry a patient over his morning cough, bath, and toilet, with a good appetite for breakfast. I have repeatedly seen this simple expedient make a great difference in the comfort of the whole day.

Alcohol, in such form and quantity as careful observation of the individual patient shows is best tolerated, is indicated in most, though not in all, cases. Any toxic effect is to be avoided, and the influence on the appetite and digestion is to be watched; there is room for the exercise of much judgment in the use of this form of food, and that a certain amount of alcohol is, under certain conditions, a food, I have myself no question.

With forced feeding after the manner of Debove I have no personal experience, and dismiss the subject of diet with the repetition of the axiom that in phthisis the physician should see to it that his patient takes all the nourishment he can digest.

The moral management of the case requires a few words. Here there is scope for the most delicate tact and the most intimate knowledge of human nature. Some patients need to be frightened, some to have their fears allayed. Let science clarify and sharpen our vision; let it not render us so hypermetropic that we do not see distinctly the individual in the patient before us. I think we are sometimes inclined to forget what a powerful therapeutic agent prognosis may be. Let us give the patient the benefit of every doubt, remembering that the prognosis represents our opinion, not inevitably the truth. An unfavorable opinion should often be reserved for a near and judicious friend, if the patient be so fortunate as to have one. All patients are not so tenderly considerate of their physician's mistakes as was the young lady who recovered after she was given up by her doctor, and ever thereafter, when she met him, blushed for shame. Occupation is another branch of moral treatment which must not be lost sight of.

Dress need not detain us long. Consumptives are apt to err on the side of too many and too heavy clothes, keeping the skin in perpetual action and wearying the body by mere weight. The ordinary house-dress of the average man in our climate in the winter season weighs eight to ten pounds. Let the consumptive wear wool or silk next the skin from the neck to the toes, and let him change them frequently; a change of stockings several times in the day will often obviate the discomfort of cold feet. It is important, especially with the poorer class of patients, to insist on wool, and warn them not to allow the shopkeeper to pass off a cotton for a woolen garment.

Too much stress can scarcely be laid on the importance of fresh, pure air. Carbonic acid and carbonic oxide are poisonous enough to well people, but how vastly more deleterious to those suffering from a constitutional disease manifesting itself in the lungs! Fortunately, sounder ideas prevail on this point than was formerly the case, but there is still room for improvement. The apartments occupied by the patient should face the south if possible; it seems to be thought by some that the exposure of a bedroom is of no consequence, as if a third of the life of a healthy person were not passed there. An open fire of wood or soft coal should be kept up in the living-room if possible, and ventilation should be carefully provided for. In severe or windy weather a simple frame fitted to the window and covered with flannel can be put in at the top, a weather-strip on the lower edge of the upper sash preventing the rush of cold air which would otherwise occur between the sashes. Fresh air can thus be constantly introduced without causing any appreciable draught. Equal solicitude should be given to the ventilation of the sleeping-room. I am often struck by the appearance of the houses in our most fashionable streets. In streets running east and west land is apt to be higher in price on the north side, which, of course, alone gets any sun during more than six months of the year. Of shades and curtains there are often half a dozen series, and during the forenoon the shades are pulled down and fastened at the bottom that the precious furniture and carpets, more highly valued by the owner than health, may not be faded; the sun is paid for and then excluded for the sake of the furniture. Those who can not afford delicate fabrics are better off.

So much for fresh air and sunshine in the house. Fresh air without the house is naturally considered in connection with exercise. We should insist on out-door exercise in such degree and form as the strength of the patient, the length of his purse, and the season will allow. Driving should, if possible, be in an open vehicle, which for a weak person should have a high back, and in windy weather a veil or a respirator should be worn by the occupant. People are finding out that sleighs are not the only open conveyances which can be used in winter. I believe that with proper precautions there is, as a rule, more risk of catching cold in a close than in an open carriage. Exercise in the saddle, if desirable or practicable, has the great advantage over walking that it distracts the mind as well as uses all the muscles.

We find that a certain number of those who consult us

have been doing too much. I have repeatedly seen fever greatly diminish or cease entirely after putting the patient to bed, with abundance of fresh air, for a few days. It is not enough to tell patients to avoid over-fatigue; very few know what this means. I often try to explain somewhat as follows: "A fatigue which passes away after resting an hour or so on the completion of your exercise is natural and healthy, and therefore does you good rather than harm; but if you find that, in spite of a reasonable rest, you are still tired, you have done too much." Such a rule I believe to be safe.

There is a popular idea that there is something about the night air which is particularly dangerous to consumptives—an idea which, like many of those bearing on medicine and current with the laity, probably came originally from the profession, which advances in knowledge faster than the public. The night air is all the air there is at night, and in non-malarious regions the danger of going out in the evening does not lie in the quality of the air, but in the fact that persons are at that time often tired and, consequently, more sensitive to alterations of temperature, or any other demand upon the vital forces; the bearing of this observation is sufficiently patent.

The character of the employment of the consumptive is also to be borne in mind, and an out-of-door occupation, involving no severer toil than the patient can stand, should be followed if possible. Too often this is impossible; but we must do the best we can under the circumstances.

Patients who are too weak to take any active exercise often derive great benefit from a sun- and fresh-air bath. In the country a little shed can be built, open toward the south and sufficiently deep to keep off the wind from the patient sitting in a chair or lying on a mattress. In the city an easy-chair can be placed near a widely opened southerly window. The invalid should have as many blankets or robes as he wishes. No matter how low the thermometer, if the sun shines brightly there is rarely any difficulty in keeping warm, and a small sun-shade or similar contrivance is often needed to protect the head. No artificial heat has the penetrative power of the sun, and I have repeatedly found patients, who were horrified at the idea when first presented to them, enthusiastic in their expressions of satisfaction at its practical working. In city streets people often object to this measure from a fear of appearing peculiar to their opposite neighbors or passers-by. I have found it a most valuable means of treatment for those who are debilitated from any cause.

Gymnastics, with the view of expanding the chest and promoting the absorption of diseased products in the lungs through the improved circulation thereby brought about, have perhaps not received so much attention from the regular profession as they deserve. Of course, exercise of any kind quickens the circulation; but this is not clearly understood by the laity, and the imagination is more excited by means which are manifestly directed immediately to the seat of the disease. Respiratory gymnastics have thus a double value, and precise directions are more likely to be followed than those which are purely general. I know of a "doctor" who has apparently found it very profitable to teach people how to breathe, and I do not doubt that some of his patients have found it profitable to learn; he thus prevents and cures consumption, reduces the weight of those who are too fat, and augments that of those who are too lean. A grain of truth is none the less precious because it is covered with an investment of quackery.

Another and the last branch of hygiene on which I shall touch is bathing. Cleanliness is desirable in itself, and it is quite as important for the phthisical as for the healthy to maintain a proper action of the skin. After a warm bath, unless it is followed by a cold douche, exposure to cold is to be carefully guarded against. A cold bath is a powerful tonic; but how are we to determine in a special case the proper temperature? Of course, in many cases cold baths are out of the question, but probably not in as many as is generally supposed. It is the reactive power of the patient rather than the thermometer which should decide the temperature of the cold bath; the colder the better, provided that thorough, prompt, and persistent reaction follows, promoted by a brisk rubbing with a coarse towel or a flesh-brush. The use of a cup of hot bouillon before the bath has already been alluded to, and reaction may often be further aided by the addition of rock salt or some other cutaneous stimulant to the water. That the systematic study of hydro-therapeutics as one of our weapons against debility will receive more attention in the future than it has in the past, I have no question.

The medicinal treatment may be divided into the general or curative, and the symptomatic or palliative, the object of the former being to stimulate and improve the general nutrition, that of the latter to check as they arise such symptoms as militate against the recovery or the comfort of the patient. Such a division may be artificial, but, for our present purposes, is convenient.

If we always bear clearly in mind the fact that our aim in giving general medicinal or tonic remedies is simply to promote assimilation, and thus put our patients into a condition more favorable to recovery or less favorable to the rapid advance of their disease, among other advantages we are apt to choose more judiciously the special form of tonic which is most likely to be of service. Cod-liver oil, either pure or in one of the numberless disguises which it is made to assume, and some of which certainly have their places, needs no commendation from me. It is, perhaps, a food rather than a drug; but a food which demands a certain amount of digestive power, and we all see it prescribed when it does more harm than good, for the very simple reason that digestion is not equal to it. With many physicians the diagnosis phthisis is followed by the prescription oleum morrhuæ as the thunder follows the lightning. "The doctor told me to take cod-liver oil, but I can't keep it on my stomach," said a feverish young girl without appetite who consulted me only yesterday. In my experience this remedy is generally to be avoided if the tongue be coated and the appetite poor; if, in addition, there be fever, the case is still clearer. The fever requires always fresh air, often rest, with quinine or another antipyretic, and the stomach a bitter tonic, as a rule, combined or not with a laxative, according to circumstances. After a week or two

of such treatment the appetite and digestion are often so much improved that cod-liver oil is borne. If there is any doubt as to its toleration, it is better to begin with teaspoonful doses and gradually increase to the full dose as warrant is found for doing so, the full dose being much larger than most of us have been in the habit of using, if the views of Jaccoud are correct. If the pure oil is well borne, I believe it to be better than the more palatable though weaker preparations, and the remedy is not to be thrown aside without a fair trial, inasmuch as a stomach which is rebellious at first sometimes accepts the situation with apparent cheerfulness after a few days' cautious persuasion. It is not needful that I should enumerate or dwell upon the various emulsions, etc.; the advertising pages of our journals, circulars, and the periodical visits of the affable gentlemen with hand-bags, remind us of them sometimes in moments when we would fain forget them. The fact remains that cod-liver oil pure, or never so skillfully emulsified, is worse than useless unless it can be digested; if it can be digested, it is a most valuable form for the administration of fat, a material which long and wide experience has shown to be especially indicated in consumption.

Jaccoud recommends highly glycerin, ℥ jss.–ij daily, as a substitute for cod-liver oil when there is fever.

Ferruginous tonics are sometimes of use for short periods if there is notable anæmia, but are contra-indicated by a coated tongue and sluggish bowels. Arsenic, on the other hand, either in solution or pill, has a much wider application than iron in phthisis, and should often be continued for long periods. The dose should be as large as is perfectly well borne, and it is sometimes well to omit it for a week and then resume. It interferes in no way with the administration of cod-liver oil or glycerin. The diastatic tonics and the hypophosphites also have their place, and often seem distinctly to aid a feeble digestion, thus contributing toward a gain in flesh and strength.

The leading symptoms which call for interference, and to which I shall briefly call your attention, are cough, pain, night-sweats, diarrhœa, and hectic with its attendant nervousness.

Patients often say to us, "Doctor, I have taken your medicine, but my cough is no better," the cough representing to them the disease. In a semeiological sense they are largely right, but in a therapeutic sense very far wrong. When the cough ceases entirely the patient is at the door either of recovery or death; but we know, even if our patients do not, that, as long as there is mischief in the lung, cough must persist. How often do we see consumptives who, generally on their own notion or acting on the suggestion of friends, but, unfortunately, sometimes in accordance with medical advice, are taking cough mixtures to their detriment! In advanced cases, which must sooner or later prove fatal, such an error is of less consequence; but in early cases the effect on the appetite and digestion is often disastrous. Coughing may be very hard work, but before we interfere with it there is one main question we should ask ourselves: Is the cough in the case before us useful or needless? I speak of cases relatively, not absolutely. A cough which is followed by expectoration is not entirely in vain, while that which is simply irritative wears out the patient. The former is not to be checked by any means which involves the risk of impairing the digestive power unless it provokes vomiting or breaks up the night's rest, which is of such vital importance that we are justified in seizing the two-edged-sword opium to obtain it if milder means fail. The surest way to diminish excessive expectoration is to pay close attention to hygiene and diet, though suitable inhalations will sometimes help. The type of the useful cough is that which occurs on waking in the morning, and which clears out the secretions that have accumulated during the superficial respiration of sleep. The value of a hot drink, which with a spirit-lamp at the bedside and five minutes' time is ready, as an expectorant at this time has been already spoken of. If this is not sufficient, a little alcohol or a stimulating expectorant, like carbonate of ammonia, can be given in addition.

The teasing and irritative cough, on the other hand, it is our duty to check if we can, but by the mildest means at our disposal which will accomplish our object. Oftentimes I have found chloroform-water stand me in good stead; but there are cases in which the narcotics, and especially morphia, must be used; the great danger of morphia is that it is so efficient in relieving cough that we are tempted to use it indiscriminately, thus doing great harm. One of the most distressing forms of cough met with in the phthisical is that hard variety which leads to vomiting, consuming the patient like a candle lighted at both ends; this generally calls for opium in some form, though it is well to try the effect of an alcoholic stimulant first. Especially in those cases with sharply localized pulmonary lesions, counter-irritation over the seat of the disease will often economize drugs and the stomach alike. The ammonia blister is a favorite form with me.

For the thoracic pain which is apt to be more or less pronounced at times in nearly all advanced and some early cases, and which is sometimes rheumatic or neuralgic, sometimes pleuritic, we are called upon to prescribe. Counter-irritation with mustard, chloroform, a liniment, croton-oil, and the like, generally proves sufficient, though here again we are sometimes forced to use opium. When the pain is fairly localized I find that the application of a dry cup or two, a simple remedy which has gone too much out of fashion and of which any untrained attendant can readily be taught the use, is often followed by marked relief.

Another symptom which demands interference is night-sweat, sapping the strength of the patient and marring his sleep. Sometimes it is a very easy matter to control this overaction of the skin, sometimes it is very difficult. Hence it is well to have many strings to our bow; we are not infrequently compelled to try successively aromatic sulphuric acid, oxide of zinc, ergot, atropia, quinine, or Dover's powder internally, or dusting powders, sponging with acids, alkalies, alcohol, or tincture of belladonna externally, before we meet with success. If the patient can bear it, active friction or shampooing of the skin is often desirable. I have given a good deal the pill used in the Victoria Park Hospital containing morphia and atropia, combined with a little capsicum and a laxative if required; night-sweats and

cough are both controlled by it, but my objection to atropia lies in the difficulty of so adjusting the dose that the desired effect on the skin is obtained without producing an undesirable degree of dryness of the throat. In two cases I have succeeded with picrotoxin after having tried in vain every other remedy of which I could think.

There can be no more question as to the propriety of trying to relieve diarrhœa than there is with regard to pain and night-sweats. When the loose discharges depend on ulceration, and still more when they depend on amyloid disease of the intestine, they are apt to be difficult to restrain; and yet in some cases of tubercular, as of typhoid ulceration, so far from diarrhœa being present, there is constipation. It is needless to say more than that the treatment is by astringents and opium, the particular remedy in any given case depending on the urgency of the symptom, trial, and any known peculiarity of the patient. In cases where there is any hope of recovery, if we give opium we should strive, while we give enough to attain our end, to give no more than is necessary.

For nervous irritability, whether manifested by a worried but healthy adult, a teething child, or a phthisical person, a plentiful supply of cool, fresh air is the first indication.

Against the fever of phthisis antipyretics have, as far as I know, been but little employed in this country. I certainly have made no systematic use of them myself. The fever is not the disease, and the cases must be very rare in which a diminution of the pyrexia for a few days may make all the difference between recovery and death, as is sometimes true of the more acute infectious diseases. At the same time fever works to the detriment of the patient in two ways—diminishing his income and also squandering his capital. Therefore, if we can combat it without destroying what little digestive power it is apt to leave, clearly our duty is to do so, and I propose to give the method which Jaccoud thinks has yielded him admirable results a thorough trial. It is perhaps scarcely fair, either to him or to you, to try to describe in a few words what his method is; but the gist of it is the administration of large doses of quinine for inflammatory fever by the mouth or under the skin, the hydrobromate being always chosen for the latter avenue of introduction into the system, while for the fever of absorption large doses of salicylic acid by the mouth or salicylate of soda hypodermically, if the stomach is irritable, are chosen. Whether we shall all find it as easy to differentiate the forms of fever in phthisis as does Jaccoud I do not know, but the subject of fever is far too large for our present opportunity.

My slight sketch of the home treatment of consumption is now finished. The different aspects of the question afford material for a dozen detailed pictures, and there are two important lines of treatment of which I have purposely omitted all mention—inhalation, notably by antiseptics and oxygen, and the use of artificially compressed and rarefied air. Perhaps I am wrong, but the published reports of the experience of Pepper, Beverley Robinson, and others, has not encouraged me to try antiseptic injections into the lungs; nor have I ever practiced the free incision and drainage of pulmonary cavities.

DISCUSSION.

Dr. P. Kretzschmar indorsed the remarks of Dr. Shattuck. There were some points which perhaps deserved further consideration. One related to the sleeping-room. As we all knew, one third of the time of every human being was spent in the sleeping-room, and he therefore thought that more attention should be given to this matter in the hygienic treatment. He had in mind particularly the question of the size of the sleeping-room, the question of the consumptive sleeping with other persons, and the question of leaving the windows open at night. The home treatment of consumptives related especially to the poor, and here we were apt to find five or six persons sleeping in a small room badly ventilated. He thought more could be done by the administration of pure air if attention were given to the ventilation and size of the sleeping-room, where the patient spent a third of his life, than by other means. He, of course, approved of the author's remarks concerning the ventilation of the sleeping-room during the day. The second point was, Should we not advise our patients, especially those inclined to phthisis, against sleeping with others? A third point was, we did not usually pay sufficient attention to the frequent and thorough removal of the sputa from the sleeping-rooms. In addition to the remedies mentioned, he recommended cold sage-tea before going to bed.

Dr. Robinson said he did not wish in any wise to criticise the paper as far as it went, for he agreed with Dr. Armour, who considered the paper an admirable presentation of the subject, but he regretted that the author had not mentioned three modes of treatment which he believed physicians might find of advantage in the treatment of phthisical patients at their homes after other methods had failed. The first was forced feeding, giving patients more food than they craved, and even more than the stomach could digest if the food was swallowed. The second method related to intra-pulmonary injections; the third to antiseptic inhalations, with regard to which he had presented his views in a paper to-day. These methods had been tried in St. Luke's Hospital during the past winter. A young man came into the service of Dr. Ball six or eight months ago, afterward into Dr. Kinnicutt's service, and finally into his (Dr. Robinson's). On admission, there was evident pulmonary infiltration at the apices, and the stomach was absolutely intolerant of the smallest quantities of food. Nearly everything was vomited. By washing out the stomach and pouring food into it through a soft tube they were enabled to give the patient nutriment, and increased his weight at least six or seven pounds. Beyond this increase in weight, the patient's phthisical condition was in no sense ameliorated. We had to take such a case for what it was worth. We certainly could not take it as showing that phthisis was made better even by improved nutrition; but it showed that we could increase the patient's weight and thus better his condition.

With regard to injection of infiltrated lung areas, he could only repeat what he had before endeavored to emphasize, namely, that there were certain cases in which we were unable to arrest cough by other means, while this treatment benefited cough and local congestion.

One more word, which he knew to be heterodox, but which he believed nevertheless to be true. He had had charge of a good many phthisical patients at the Out-patient Department of the New York Hospital, and he could say that certainly very few of those persons having infiltration of the lungs were benefited to any considerable degree by ordinary methods of treatment.

Dr. Shattuck, in closing the discussion, said he cordially agreed with all Dr. Kretzschmar had said. He had found it

hard to tell, in so short a paper, what to say and what to leave unsaid. With regard to what Dr. Robinson had said concerning forced feeding, he was glad to hear about it, and to know that it had been tried in New York. He had not mentioned it in his paper because he had had no personal experience with it. Inhalations and treatment with compressed and rarefied air he had left out purposely, because they were large subjects and he knew there were to be papers specially devoted to their consideration. With regard to injections into the lungs, he had read one paper on the subject by Dr. Robinson, and the impression which he got from it was that he did not do the patients any harm, but he could not say that he did them any good, and it was not pleasant to have the needle stuck into one unless it promised some good result.

THE RADICAL TREATMENT OF SYPHILIS.

By W. A. HARDAWAY, M. D.,
ST. LOUIS.

The article in this journal for July 11th, by Dr. Leuf, on the "Eradication of Syphilis during the First Stage by Surgical Means," will perhaps recall the fact that a paper of similar import was published by me in the "New York Medical Journal" for December, 1877. In von Ziemssen's "Handbuch der Hautkrankheiten," Neisser, in the article on syphilis, credits my paper on the extirpation of lymphatic glands in the radical treatment of syphilis to the "American Journal of the Medical Sciences" for 1877.* As a matter of fact, however, this subject was presented by me originally in the shape of a thesis for graduation in the year 1870. It was subsequently published in the "St. Louis Medical and Surgical Journal" for May, 1872, then enlarged and read before the American Dermatological Association in 1876, and afterward printed in the "New York Medical Journal," as stated above.

Before concluding, I should like to trespass on your space for a few general statements. Hill's case, well known to syphilographers, in which he cauterized a laceration of the frænum, made during violent intercourse, twelve hours after its occurrence, and with a negative result as to prevention of systemic infection, together with the oft-quoted inutility of the complete destruction of the vaccinal *bouton*, have been paraded time and again as proofs, both positive and analogical, of the utter futility of any local measures in the suppression of constitutional symptoms. While I am far from denying that the *complete* and *sufficient* destruction of the initial lesion, at the right time and in the right way, may, under certain circumstances, avert general syphilis, still I long ago said: "I believe that in a certain number of cases destruction of the initial lesion would prove futile, as I am of the opinion that the virus is soon carried to the lymphatic glands, as is evidenced by these glands undergoing the same processes as obtained in the primary sore, and this would explain why total destruction of the inoculated parts has generally proved unavailing." In the section on treatment, in the paper referred to, which I shall take the liberty of quoting at length, I made the following statements:

"As a logical result of the views which have been expressed as to the pathology of syphilis (that is, absorption by the lymphatics), it has long seemed to me that an early extirpation of the enlarged lymphatic glands contiguous to the initial lesion would in some instances avert constitutional infection. This would certainly be, to say the least, as legitimate an operation as excision of the chancre itself, which is looked upon favorably by some excellent authorities, although, even from my standpoint, I would regard this latter procedure as generally unavailing for reasons already given. By writers such as Lee, Lancereaux, and others, who do not deny that the syphilitic virus is carried to the glands by the lymphatic vessels, this operation might still seem to be justifiable, as depriving the blood of one of its sources of infection. While not bearing directly on this subject, but still of interest in this connection, we find Niemeyer writing that 'it is quite possible that at no distant day the danger of pulmonary tubercle, which the presence of the cheesy residua of enlarged glands produces, will take a place among the indications for the extirpation of peripheral lymphatic tumors.' It would be advisable to remove enlarged lymphatics following the initial sclerosis at the earliest period practicable, when they had first begun to indurate. . . . Again, if it be admitted that lymphatic glands remain as foci of infection, . . . it would not be bad practice to remove them."

Some years after the foregoing was first written I had the good fortune to read the very remarkable papers by M. Raynaud, entitled, "Recherches expérimentales sur l'infection et l'immunité vaccinales," "Gazette hebdomadaire," No. 29 *et seq.*, tome xvi, 1879. These experiments of the late distinguished French physician, which seem to be little known, but, so far as I am aware, never contradicted, appear to my mind to be conclusive so far as vaccinia is concerned, and also by a logical analogy for syphilis. As I have already occupied too much of your valuable space, I shall content myself with merely giving an outline of Raynaud's experiments. Raynaud has demonstrated (*a*) that the virus of vaccinia is conveyed to the system at large by way of the lymphatics; and (*b*) that extirpation of the vaccinal *bouton* alone is ineffectual as regards general infection, but that this end is completely gained when (for reasons that he clearly indicates) both the *contiguous glands* and the vaccinal lesion are suppressed.

* The whole title of the paper is "The Lymphatic Theory of Syphilitic Infection; with a New View of the Relation between the Chancre and Chancroid, and Suggestions for the Treatment of Syphilis."

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & Co.
Edited by FRANK P. FOSTER, M. D.
NEW YORK, SATURDAY, SEPTEMBER 26, 1885.

THE INTERNATIONAL MEDICAL CONGRESS.

WE are close upon the termination of the period of thirty days that the New York meeting of the American Medical Association's committee laid down as the time within which it would receive back into the fold any of the gentlemen who had declined to figure in its organization of the International Medical Congress, but who might be willing to withdraw their declinations. In the course of a week from now the period alluded to will have all but expired. So far as we know, only one person has seen fit to respond to the committee's overtures, while, on the other hand, the work of declination is steadily going on, and, as will be seen by announcements elsewhere in this issue, has been taken part in latterly by some of those to whose continued support the committee must have attached the utmost importance, and upon which it must have counted quite confidently. Not only has the committee thus signally failed to recall those who declined to share its fortunes, and to prevent others from joining them, but it is plainly evident from the expressions made use of in the committee's official report of its proceedings that it has at last come to recognize the fact that it must proceed with great caution in the work of making appointments, lest it may appoint gentlemen only to find them declining at the earliest opportunity.

It is manifest, therefore, that the committee has utterly failed to repair in any degree the breach of concord which its creation precipitated upon the American profession, and which, in the view of the great majority of well-informed and fair-minded men, has entirely done away with the possibility of a successful meeting of the Congress in this country in 1887. It was not to be expected that the committee would be able, even if it was willing, to take measures calculated to restore the harmony necessary to success; for it could not, of course, go counter to the implied instructions under which it acted. Having done its best to carry out those instructions at its Chicago meeting, it might at one time, when its efforts were first shown to have demonstrated the impracticability of reconciling the American Medical Association's usurpation with the possibility of a successful meeting of the Congress, have gracefully declined to proceed further in its thankless task. Instead of doing so, it chose to indulge in further attempts to accomplish the impossible, and it also took occasion—or occasion has been taken in its behalf—to inform the profession that its (the committee's) course was in no sense a compromise. Compromise it certainly was not, nor was it in any way conciliatory. As the committee, therefore, has no disposition to conciliation, it is useless to expect now that it will under any circumstances admit that its creation was detrimental to the proposed Washington meeting of the Congress. The question arises, then, whether it is incumbent upon the officials of the Congress to wait much longer before withdrawing the acceptance of the American invitation. Our own conviction is, that both the interests of the Congress and those of the American profession would be decidedly furthered by prompt action on the part of our European colleagues.

MINOR PARAGRAPHS.

THE NEW BRITISH PHARMACOPŒIA.

FROM the comments of our London contemporaries on the new British Pharmacopœia, we learn that certain changes of nomenclature have been made which bring it into close conformity with our own pharmacopœia, especially in the matter of the proximate principles of vegetable drugs. Such words as morphia, strychnia, atropia, etc., have been given up, as was done in our pharmacopœia three years ago, and we trust that they will soon disappear from medical writings. As with us, the alkaloids are now to be known by names ending in *-ina*, while the termination *-inum* is given to neutral principles. Now that the British and the United States Pharmacopœias are at one on this point, and in accord with the practice of contemporary chemists, we trust that their example will soon be followed in the pharmacopœias of other nations. As regards nomenclature, the oleates seem to have been put upon a different footing from other salts with names ending in *-ate*, for, while we read of sodii salicylas, sodii sulpho-carbolas, etc., we find oleatum hydrargyri, and so on. Paraffinum durum and paraffinum molle, which we take to mean respectively paraffin and "vaseline," seem to us to be preferable to our own terms for those substances. Among the coca preparations we find cocainæ hydrochloras and lamellæ cocainæ.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 22, 1885:

DISEASES.	Week ending Sept. 15.		Week ending Sept. 22.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	48	9	59	13
Scarlet fever	24	1	15	1
Cerebro-spinal meningitis	5	5	4	5
Measles	1	0	4	2
Diphtheria	38	18	46	30
Small-pox	2	0	2	2

Small-pox in New York.—It is reported that a woman suffering from small-pox was found in a house in Grand Street. It is probable that other cases may result, as a number of boarders left the house as soon as the nature of the disease was discovered.

Small-pox in Canada.—The United States Consul-General reports to the secretary of the National Board of Health the number of cases of small-pox to September 15th as follows: Province of Ontario.—Cornwall and vicinity, 2; Toronto, 2; Ottawa, 2. Province of Quebec.—St. Johns, 2; Farnham, 20 cases and 6 deaths since July 20th; Coteau Landing, 3; Longueil, 1; Three Rivers, 2. In villages in consular district, 8. Montreal, September 10th to 16th.—Cases reported 10th to 12th inclusive, 132; authenticated by Health Department, 54. Deaths reported from September 10th to 12th inclusive, 164. By order of the Board of Health, information concerning reported cases is

now withheld, on the ground that the information on which the reports are based is not reliable.

The Plymouth, Pa., Epidemic of Typhoid Fever, which it was supposed had come to an end, is reported to have again made its appearance. One case has already proved fatal, and several new cases have been reported.

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, August 29th: *Montreal, Canada.*—For the week ending September 2d: 230 cases of small-pox and 96 deaths. For the week ending September 9th: 192 cases and 120 deaths. The number of cases includes only those reported by physicians or which have been verified by the Health Department. During the three days, September 7th to 9th inclusive, 80 cases were reported, as against 112 during the three days, September 3d to 5th. *Toronto, Canada.*—Up to September 5th there were only 4 cases of small-pox reported. *Three Rivers, Canada.*—September 5th: One case of small-pox reported; disease contracted in Montreal. *Concord, N. H.*—For the week ending September 10th: The secretary of the State Board of Health reports that there are 4 cases of small-pox in hospital at Manchester, the disease being confined to the members of a French family recently arrived from Montreal. There have been no known exposures to these cases, and precautions are being taken to prevent the spread of the disease. *Havana, Cuba.*—For the three weeks ending September 10th: 92 cases of yellow fever and 29 deaths. *Cardenas, Cuba.*—September 5th: Free from epidemic diseases. *Matanzas, Cuba.*—September 9th: Intermittent fever prevalent. *Cape Haytien, Hayti.*—In good sanitary condition. *St. Thomas.*—August 31st: 2 cases of yellow fever, in a family recently arrived. No cases among the shipping. *San Domingo.*—September 3d: Free from epidemic diseases. *Pernambuco, Brazil.*—August 7th: 1 death from yellow fever. *Acapulco, Mexico.*—September 3d: Pernicious fevers prevalent. *La Guayra, Venezuela.*—August 29th: Free from epidemic diseases. Yellow fever in *Caracas* abating. *Callao, Peru.*—From July 18th to August 15th: 5 cases and 4 deaths from small-pox. During the week ending August 8th 1 case of yellow fever was reported. *Guyamas, Mexico.*—August 23d: No epidemic diseases. Sanitary condition good. *Cartagena, Colombia.*—August 28th: Consul reports sporadic cases of yellow fever. *London, England.*—For the four weeks ending September 5th: 26 deaths from small-pox and 12 from cholera or choleraic diarrhœa. The number of cases of small-pox in the hospitals is 295 against 310 August 29th. *Bradford, England.*—For the week ending August 22d: 1 case of small-pox reported; the disease is also reported as prevalent at *Ilkley*, a neighboring health resort. *Paris, France.*—For the two weeks ending August 29th: 11 deaths from small-pox; 29 cases treated in hospital. *Bordeaux, France.*—For the month of August: 4 deaths from small-pox. *Antwerp, Belgium.*—For the four weeks ending September 5th: 13 cases and 3 deaths from small-pox. *Cadiz, Spain.*—For the week ending August 29: Deaths during the week about 40 above the average. The increased mortality is due to diarrhœal disease and cholera. Officially, the port is regarded clean, and clean bills of health are issued. *Gibraltar, Spain.*—For the three weeks ending August 29th: 24 cases and 12 deaths from cholera. *Malta, Spain.*—For the two weeks ending August 15th: Free from cholera and small-pox. *Barcelona, Spain.*—From August 1st to 10th: 125 deaths from cholera; from August 10th to 31st: 581 cases and 335 deaths from cholera. *Valencia, Spain.*—For the two weeks ending August 29th: 56 cases and 24 deaths from cholera; 5 cases and 2 deaths also occurred on a Danish vessel in the harbor, from Barcelona. *Tarragona, Spain.*—For the week ending August 29th: 22 cases and 8 deaths from cholera. *Genoa, Italy.*—For the two weeks ending August 30th: 6 cases of small-pox and 2 deaths. *Venice, Italy.*—For the two weeks ending August 22d: 8 deaths from small-pox; diarrhœal diseases also prevalent. *Treiste, Austria.*—For the three weeks ending August 29th: 50 cases and 10 deaths from small-pox; the disease is said to be increasing. *St. Petersburg, Russia.*—August 1st to 15th: 3 deaths from small-pox. *Warsaw, Russia.*—For the two weeks ending August 22d: 12 deaths from small-pox. *Bombay, India.*—For the month of July: 41 deaths from cholera. *Calcutta, India.*—For the three weeks ending August 8th: 89 deaths from cholera. *Hioga, Japan.*—From July 1st to 25th: 4 deaths from small-pox. *Osaka* and *Hioga, Japan.*—August 8th: No cases of contagious or infectious disease reported. During the first six months of the current year the following cases and deaths from infectious diseases have occurred in Japan, as reported by the Japanese Central Sanitary Bureau: Typhoid fever, 7,984 cases and 2,078 deaths; diphtheria, 1,442 cases and 856 deaths; typhus, 444 cases and 78 deaths; small-pox, 4,472 cases and 1,191 deaths; cholera, 16 cases and 10 deaths. The total number of cases and deaths from cholera in Spain from March 4th to August 16th is 159,173 cases and 63,640 deaths.

The International Medical Congress.—We understand that Dr. John C. Dalton, Dr. Thomas M. Markoe, and Dr. Charles Stedman Bull, of New York, and Dr. Thomas F. Rochester, of Buffalo, have declined to hold the positions to which they were appointed in the organization.

Personal Items.—Dr. Fordyce Barker, after a summer spent abroad, for the most part in sickness, returned to New York on Saturday last. Our readers will be gratified to learn that he is now slowly recovering and is likely soon to be in his usual state of health.

Dr. Lewis A. Sayre, after an illness of about a year, has, we are happy to hear, recovered sufficiently to have been able to deliver the introductory lecture of the course at Bellevue Hospital Medical College last Wednesday.

Dr. E. G. Janeway, who has been seriously ill with pneumonia, is convalescing, and it is to be hoped that he will soon be able to resume his practice.

The American Gynæcological Society.—The following gentlemen have been elected as officers for the ensuing year: Dr. T. A. Reamy, President; Dr. T. Parvin, First Vice-President; Dr. G. J. Engelmann, Second Vice-President; Dr. J. T. Johnson, Secretary; Dr. M. D. Mann, Treasurer; Dr. F. P. Foster, Dr. J. C. Reeve, Dr. B. B. Browne, and Dr. R. B. Maury, Council. The next meeting of the society will be held in Baltimore, September 21, 22, and 23, 1886.

Buffalo General Hospital.—Miss Mary K. Howell has been appointed superintendent of nurses, to fill the vacancy caused by the resignation of Miss Lizzie Johnson.

College of Physicians and Surgeons of Chicago.—We learn that Dr. J. J. M. Angear has resigned the professorship of the Principles of Medicine.

Obituary Notes.—The death of Dr. William C. Hunter, of New York, occurred suddenly on Saturday, the 19th inst. He was born in Burke, N. H., in 1829, and was graduated from the College of Physicians and Surgeons, of this city, in 1857. He was at one time associated with the late Dr. E. R. Peaslee in the Medical Department of Dartmouth College. He was a member of the Medical Society of the County of New York, of

the New York Pathological Society, and of the New York Academy of Medicine.

The death of Dr. Francis D. Cunningham, of Richmond, Va., took place on Wednesday, the 9th inst., at the age of forty-nine. He was born in Goochland County, Va., in 1836, and was graduated from the Medical College of Virginia in 1857, attending lectures subsequently at the Medical Department of the University of the City of New York, from which he was graduated in 1859. He was a member of the Richmond Academy of Medicine, of which he was president in 1872, and of the Virginia State Medical Society, of which he was president in 1875. He was also a member of the American Medical and of the American Public Health Associations, and had made a reputation as an ophthalmologist.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 13 to September 19, 1885:*

Campbell, John, Colonel and Surgeon. Retired from active service September 16, 1885. S. O. 212, A. G. O., September 16, 1885.

Society Meetings for the Coming Week:

Monday, *September 28th:* Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement.

Tuesday, *September 29th:* Boston Society of Medical Sciences (private).

Wednesday, *September 30th:* Auburn City, N. Y., Medical Association; Berkshire District, Mass., Medical Society (Pittsfield).

Thursday, *October 1st:* New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.; Obstetrical Society of Philadelphia; Washington County, Vt., Medical Society.

Friday, *October 2d:* Practitioners' Society of New York.

Saturday, *October 3d:* Clinical Society of the New York Post-Graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

Letters to the Editor.

THE USELESSNESS OF ALCOHOL AND CHLOROFORM AS LOCAL ANÆSTHETICS.

26 West Forty-seventh Street, *September 23, 1885.*

To the Editor of the New York Medical Journal:

Sir: In the last issue of the journal I took occasion to publish some experiments showing the possibility of prolonging the anæsthetic effects of the hydrochlorate of cocaine when subcutaneously injected. I would merely add that, since the appearance of the paper in question, I have injected dilute alcohol and chloroform beneath the skin, following the methods indicated in experiments 1 and 2 [*vide* article in the journal for September 19th]. The astringent coagulating effect of these fluids, is, however, so great that they are little adapted to the requirements of cutaneous or subcutaneous injection. Moreover, this pronounced chemical action gives rise to pain, the severity of which appears to be in the direct ratio of the quantity injected. I also passed a strong India-rubber ligature about the index-finger of the left hand, and, having allowed the latter to remain dipped in hot water until the skin was pliable, I subsequently immersed it in a glass containing chloroform. Although the immersion lasted several minutes, there was little or no anæsthesia, the prick of a pin being distinctly felt. Subsequently I removed the ligature, and again immersed the finger for many minutes, but with no better results; sensibility remained practically intact.

These observations tend to dissipate the expectations of Nunnely, of Leeds, who declared that by exposure to the vapor (!) of chloroform he had been able to cause sufficient insensibility in a finger to render the performance of a surgical operation painless. On the other hand, they confirm the opinion of Simpson, who was induced, after a series of experiments, to acknowledge that he had little hope that by the external application of chloroform a degree of local anæsthesia could be induced sufficient for surgical purposes.

Cocaine, then, still remains the ideal local anæsthetic for subcutaneous purposes when re-enforced by the good offices of the tourniquet.

J. Leonard Corning.

Proceedings of Societies.

AMERICAN GYNÆCOLOGICAL SOCIETY.

Tenth Annual Meeting, held at Washington, Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1885.

The President, Dr. William T. Howard, of Baltimore, in the Chair.

Tuesday's Proceedings.

The Address of Welcome was delivered by Dr. Samuel C. Busey, of Washington, who said: "Mr. President and Fellows: I offer you the greetings of fellowship and bid you welcome as the guests of the Washington Obstetrical and Gynæcological Society. Your acceptance of the invitation to hold your tenth annual meeting in this city conferred a distinguished honor upon our young society. On the roster of fellowship the names of Atlee, Buckingham, Peaslee, Sims, Trask, Wallace, and White are marked with the asterisk of death. Then, here, at the nation's capital on this auspicious occasion, in the unity of a common purpose, let us join with you in that faith and devotion to duty which have been crowned with such marvelous success and rich rewards. You must lead, we will follow, and, when you have completed the labors of the present meeting, and the new and renewed friendships are interrupted by your return to the scenes of your daily work, if our gratitude as pupils shall be the measure of your pleasure as instructors, your second advent will not await the expiration of another decade."

The Natural Hygiene of Childbearing Life.—Dr. Busey, of Washington, read a paper with this title. The hygiene of pregnancy, he said, related to the preservation of the health of woman during the period intervening between conception and the commencement of labor. The processes of transformation, development, and growth which took place were physiological, but were, nevertheless, terminated with more or less violence and injury to both mother and child. The unavoidable mortality was, however, small. The processes of waste and repair, of growth and development, of organization and construction, were next considered. There was no border-line of health. We could not define where the physiological ended and the pathological began. The childbearing period began with puberty and ended with the expiration of the years of maturity. Fertility increased from the commencement of the childbearing period until the climax was reached, and then declined to its

extinction. The age of greatest safety of pregnancy coincided with the age of greatest fecundity. Beyond and under, the mortality increased with the increase and diminution of age, but the rate was higher with the increase beyond than with the diminution below the age of maximum safety or least mortality. The age of nubility should correspond with the age of maximum fecundity, maximum fertility, and least mortality. Puberty and nubility were not simultaneous. Too early pregnancies were to be deprecated. Nature presented the fifth quinquiniad as the period during which the laws of fecundity, nubility, and survival found their natural complement in relatively the highest perfection. First pregnancies were the most dangerous, and the danger was increased by too early and too late primiparity. The importance of lactation was next discussed. The extinction of the childbearing function protected the remaining vital forces from decay, but, if the seeds of disease had already been sown, the change of life might increase their activity. If the age of majority for women could be advanced so as to correspond with the first year of the period of maximum fecundity, popular prejudice and love of custom would sooner or later conform fashion to the law. Precocious matrimony was to be deprecated; it was the sequel of precocious puberty. In this country and in the higher walks of life the ratio of precocious matrimony was on the increase—whether equally so among the middle and lower classes, the speaker did not know. He concluded by saying that the principal object of his paper was to direct attention to this subject and to invite discussion upon it.

Dr. J. R. Chadwick had made some investigations in regard to the early appearance of menstruation in women of various nationalities in this country. In over four thousand cases he had found that American women menstruated earlier than women of other nationalities examined. Furthermore, American women of American parentage began to menstruate earlier than American women of foreign parentage. Scarcely enough observations in reference to the menopause had been made to justify absolute conclusions, but it had been found that the menopause was appearing later in American women. The fact that the childbearing period is increased both at the beginning and the end would indicate added vigor.

Dr. J. P. Reynolds, of Boston, agreed entirely with the statements made by the last speaker, and believed that the women of the upper and middle classes menstruated earlier than they did twenty-five years ago. He considered that this indicated an activity of function which would prolong menstrual life beyond the average period of cessation.

Puerperal Diphtheria.—Dr. Henry J. Garrigues, of New York, read a paper on this subject. This was a disease not referred to in the majority of text-books. It was one of the forms of puerperal fever, or rather one of the different diseases included under that term. It was distinguished by the appearance of diphtheritic exudation somewhere in the genital tract of the puerperal woman. It was accompanied by well-marked general symptoms, imperiled life, and called for active treatment. The paper was based upon twenty-seven cases treated in hospital practice and two in private practice. The characteristic feature of the disease was the diphtheritic infiltration, which was usually of a light pearl-gray color, generally appearing in small spots and coalescing or extending by involving new areas. The exudation was firmly adherent to and immbedded in the underlying tissue. It was most marked at the points where the canal became narrow. This might be explained by the more frequent occurrence of lacerations at those points. The posterior wall of the vagina was more commonly attacked than the anterior wall, which was probably due to the fact that it was bathed with the discharges from the uterus. The exudation might, however, appear on entirely healthy portions of mucous membrane, which had not been the seat of laceration. The surrounding parts were more or less swollen. The connective tissue of the pelvis was infiltrated with serous fluid and was sometimes the seat of ecchymoses. The skin was sometimes the seat of a dusky erythema, consisting of minute spots, disappearing on pressure and not elevated. In one case petechiæ as large as hemp-seed existed. These were not affected by pressure. The same patient afterward developed erysipelas. In five cases ending fatally autopsies were made. The uterus was much enlarged, sometimes reaching almost to the umbilicus two weeks after labor. The cervix, having been torn, might show diphtheritic patches or a thin gray film. In two cases large portions of the cervix sloughed and the vagina became gangrenous. The tissue of the uterus was friable and might be almost diffluent. The diphtheritic exudation might affect the Fallopian tubes. In some cases the muscular tissue of the uterus was scooped out as in dissecting metritis. This occurred in four of the cases of puerperal diphtheria. In one case the mass thrown off was four inches long, two inches wide, and one inch thick. These masses had a pyriform shape, their outer surface was of a gray color, and the inner surface of a flesh-color. They were perforated with a number of holes leading into the uterine sinuses. Under the microscope these masses were shown to consist of smooth muscular fiber in a more or less advanced state of fatty degeneration. The connective tissue was increased. Lesions were also found in other organs and occasionally in the joints. Difficult labors and a previous weakened condition of the patient predisposed to the development of the condition. The real cause of the disease was, however, an infection from without. He had never been able to convince himself that the poison passed from one patient to the other, but it seemed to be in the air of the ward. When a ward had been fumigated with sulphurous acid there would not be a seriously sick patient for weeks. That the poison came from without was also shown by the fact that, when the prophylactic treatment to which he would refer was adopted, the disease did not develop. The first symptom which showed a deviation from a normal course was usually the occurrence of fever, which mostly appeared from two to four days after delivery. Sometimes there would be a chill or chilly feelings. The temperature rose gradually as a rule. It had ranged from 100° to 107° F., the average being from 102° to 104°. Anorexia, vomiting, coated tongue, and diarrhœa showed disturbance of the gastro-intestinal canal. The patient complained of pain in the epigastrium and one or both groins, sometimes extending into the legs. Examination showed the uterus larger than it should be and quite tender. Tenderness was often also found in the groins and some swelling might also be observed. The lochial discharge was often scanty and offensive, but in some cases it had been normal. Where there was expulsion of the tissues of the uterus, there had been a purulent discharge until expulsion had been accomplished. The diphtheritic patch commonly appeared from three to seven days after delivery. It continued to spread for several days, and usually stopped in from three to eight days after the beginning of treatment. In one case the diphtheritic patches also appeared on the tongue, indicating that the disease was identical with the ordinary form of diphtheria attacking the throat. The irritation of the nervous system was shown by headache, stupor, and delirium. There was alteration of the renal secretion and sometimes painful micturition. Three patients had albuminuria. In two cases jaundice bore testimony to the perverted condition of the blood. The sweet breath and profuse sweats of septicæmia were observed twice. One patient developed painful arthritis of the elbow joint. When once the diphtheritic process was arrested, the patients recov-

ered rapidly. There was scarcely any difficulty in the diagnosis. When the injections of bichloride of mercury were employed they caused a yellow discoloration of abraded surfaces. This was strictly limited to the abraded surface, and was unaccompanied with general symptoms. When the chloride of zinc was applied to the affected surface in the treatment of the disease, a slough was caused having the color of the deposit, and the physician was sometimes at a loss to determine whether or not the disease was spreading. The point was decided by noting where the application was made and by observing the edge of the deposit. The diphtheritic deposit had a scalloped outline, while the outline of the slough from cauterization was smooth. As to prognosis, five out of twenty-nine patients died, giving a mortality of 17·2 per cent. Another might have survived, for she lived thirty-two days and died from rupture of the uterus, which had been thinned by sloughing, while an assistant was giving an intra-uterine injection. The post-mortem showed the walls of the uterus to be extremely thin. The duration of the cases ending in recovery was usually about two weeks. In cases in which a portion of the uterus was scooped out the organ was left in a weakened condition, which in future pregnancies might predispose it to rupture. In the way of prophylaxis, it was recommended to limit the vaginal examinations during labor as much as possible. The finger or hand should not be introduced into the uterus unless absolutely necessary. The delivery should be so accomplished as to avoid as much as possible wounding of the genital canal. Instruments should be used with the greatest care. The most important element in the prophylaxis was the use of bichloride of mercury as an antiseptic. Everything coming in contact with the patient should be washed in the solution of corrosive sublimate, 1 to 2,000. After this treatment was introduced only one case appeared in six months, and that was due to carelessness on the part of a resident who delivered a woman immediately after removing a macerated fœtus from another patient. After the disease appeared the treatment must be energetic. The only treatment that had given him satisfaction was that with chloride of zinc. The affected parts were touched with a solution of equal parts of chloride of zinc and distilled water. This was rather painful and an anæsthetic might be used. A warm solution of corrosive sublimate, 1 to 2,000, was used for intra-uterine injection where this was required, and subsequently a suppository of fifteen grains of iodoform was introduced. If this was done the process need not be repeated more than once in the twenty-four hours. The vagina was to be douched every three hours. The parts should be examined every day, and, if the process was not arrested, the application of chloride of zinc was to be repeated. If the disease was limited to the vagina and vulva, the intra-uterine treatment was omitted. Ergot was also given with the purpose of causing contraction of the uterus. Morphine, quinine, and digitalis were used as indicated. High temperature was combated with sponge-bathing, salicylic acid, and, if necessary, the rubber coil. Carbolic acid was also given sometimes combined with the compound tincture of iodine. If the temperature was not very high, warm poultices were preferred. Where there was diarrhœa, warm poultices were also considered preferable. Samples of the occlusion bandage to be used after labor were exhibited. They consisted of a pad of absorbent cotton wet with the corrosive-sublimate solution, over this a piece of oiled muslin or gutta-percha tissue, and over all another piece of absorbent cotton and a piece of muslin or flannel to attach it to the binder.

Dr. W. T. Lusk, of New York, had treated, ten years ago, one hundred and fifty cases of this affection, with twenty-eight deaths. The epidemic could be traced to a patient brought into the hospital after a long labor. She was suffering at the time from a syphilitic ulcer of the vulva, which was excessively inflamed. The child was extracted with forceps and the inflamed perinæum was torn. Soon after this the diphtheritic deposit appeared, and the whole ward was infected. The first cases were the result of transference from the patient, for the question of contagion was not then recognized as it was now. After a time great care was taken to avoid every possible source of contact, but the disease continued, and could be only explained on the supposition that the air of the ward was filled with germs. In the first cases, the treatment consisted in the application of equal parts of solution of persulphate of iron and compound tincture of iodine. The disease usually began with a certain amount of mildness and gradually became more severe. Of the first twelve patients only two died, while in the second set of twelve only two recovered. In the progress of the epidemic the entire system seemed to be affected, even before the advent of labor. Since the adoption of the use of corrosive-sublimate injections he had not seen a case of puerperal diphtheria. Neither had he had a death from fever, nor any cases of fever, even the old-fashioned "milk-fever" being absent.

Dr. H. P. C. Wilson, of Baltimore, was averse to the uso of bandages of any kind after delivery, preferring to have the napkins placed under the patient so as not to obstruct the free flow of the discharge, and to use frequent washing of the vagina with antiseptic solutions.

Dr. W. L. Richardson, of Boston, had treated many cases of puerperal diphtheria with ill success, until the appearance of Dr. Garrigues's paper. After the use of the pad and the corrosive-sublimate solution for the hands of the attendants and nurses was begun, the hospital had been almost entirely free from the disease. There had been no death since these measures were adopted.

Dr. John Byrne, of Brooklyn, asked as to the frequency of cicatricial distortions of the vagina after diphtheria, and related an interesting case of that sort.

Dr. Garrigues thought that the indorsement of Dr. Lusk and Dr. Richardson would be sufficient to induce others to try the occlusion pads. During the year preceding the introduction of the new method of treatment the mortality was nearly seven per cent. During the next year, with the new method of treatment, the mortality was one and a half per cent. During the second year it was less than three fourths of one per cent. In the institution in which these observations were made there were many disturbing elements, one of the most important being its connection with a large general hospital. In this new method of treatment the antiseptics were applied only to the outside in normal cases. Only in abnormal cases were vaginal and intra-uterine injections employed. He had only seen two of the patients subsequent to recovery. In one there were great shortening and narrowing, but during pregnancy softening took place and the labor was quite easy. The second patient was pregnant and the vagina appeared to be in good condition.

Four Cases of Oophorectomy, with Remarks.—Dr. Joseph Taber Johnson, of Washington, read a paper with this title.

Case I.—Miss M. had suffered severely from chronic oöphoritis and menstrual epilepsy. She was twenty-nine years of age and had suffered for fourteen years. There was constant pain in both ovaries, but most of the suffering was on the left side. For two weeks out of every month she was under the care of an attendant, her education had been neglected, and she was in a most deplorable condition. She had been under the care of skillful physicians, and almost everything had been tried. Oöphorectomy was therefore decided upon and performed August 17, 1882. Both ovaries and one Fallopian tube were removed. For several months she had no periods and no spasms. Gradually her menses returned and with them the convulsions in

milder form. She was now menstruating with more regularity than before the operation.

Case II.—Miss W., aged twenty-one, took a severe cold at the monthly period five years before coming under observation. Since then she had suffered from chronic oöphoritis. She also had leucorrhœa and a displaced uterus, for which she was treated without material benefit. The reader treated her for three months without benefit and then removed the ovaries. She made a rapid recovery and had since been free from pain.

Case III.—Miss S., aged twenty-four, had been a great sufferer from dysmenorrhœa and reflex symptoms. She suffered with burning pain in the abdomen and head for ten days preceding menstruation. For several months there had been no flow, but the distressing symptoms continued. Both ovaries and tubes were removed. She made a rapid recovery and continued healthy.

Case IV.—Mrs. ——, aged forty, the mother of three children, had suffered with pain in the region of the left ovary for twenty years. She had a lacerated cervix and perinæum, which had been restored without improving the symptoms. She had been under treatment for ten years, and was practically bedridden for three weeks out of every month. She wished to have the ovaries removed, but the author advised her to wait five years longer until the menopause, which would accomplish the same result. She, however, insisted on the operation, and he performed it last February. She did well for three days, when vomiting set in, and she died exhausted on the sixth day. The speaker then referred to the great importance of an early diagnosis in such cases in order that the operation might be performed before numerous adhesions had taken place and before the general condition had become so depressed, referring to the statistics of various operators in confirmation of his statements. He thought that many patients who were now lost from prolonged operations, on account of numerous adhesions, might be saved if there were means by which an early diagnosis could be made.

Dr. R. S. Sutton, of Pittsburgh, thought that everybody admitted that a woman with a cystic tumor of the ovary was doomed to death if the tumor was not removed. But, when she was suffering from some disease of the ovary which did not give tangible evidence of its presence, the surgeon often had difficulty in deciding as to the question of operation. Was the woman to be allowed to go on suffering because evidence of disease that would justify an operation could not be obtained? It was better to give the woman the benefit of the doubt and open the abdomen and examine the organs. He did not think that any one could tell the exact condition of the ovaries before opening the abdomen. It had now come to be the practice, in obscure conditions for which no explanation could be found and in which it was probable that the ovaries or tubes were at fault, to do an exploratory operation. As a rule, exploratory operations were safe. He had yet to open the first abdomen and fail to find disease of the ovaries or tubes.

Dr. W. H. Baker, of Boston, feared that there was great danger of the pendulum swinging too far and the operation being performed too frequently. He would not discourage the operation in properly selected cases. Greater skill was shown in curing these patients without the removal of the organs. A better understanding as to when the operation should be performed and when not would be arrived at by studying the organ itself very carefully in those cases in which it had been removed. In all reports of the operation there should be an accompanying report of the microscopical examination. The question of early diagnosis had been referred to. It was a matter of the greatest importance. The ovaries and tubes were not the easiest organs to examine. Even where the ovaries were adherent to surrounding tissues it was often extremely difficult to determine this fact, and an exploratory operation might be the only way of determining it. Where an exploratory incision had been made, and the organs found healthy so far as their gross appearance was concerned, he insisted that they should be put back and the abdomen closed, even if the woman suffered excruciating pain with menstruation.

Dr. T. A. Emmet, of New York, said that he was not an advocate of the operation, and he thought that more harm than good had been done by its performance. There were cases where it must be done. Where there was salpingitis with the tubes filled with pus, the operation was certainly indicated. That it should be done, as it frequently was, for the relief of so many symptoms was a reproach on the profession. He did not advocate the opening of the abdomen for the purpose of making a diagnosis. If the diagnosis could not be made before hand, he did not think it justifiable to run the risk of opening the abdomen. For three years he had been looking for cases in which he considered the operation indicated, and had seen but two such cases. One was a typical case in which there had been several attacks of peritonitis following gonorrhœa. Both tubes were as large as the wrist, and the history indicated the existence of pus. An operation was urged, but the patient refused. For five months there was no improvement. The treatment consisted of hot-water injections, keeping the bowels regular, daily applications of iodine, and attention to the general health. After several months the tubes began to diminish in size, and in the course of a year the accumulation had entirely disappeared and she left the hospital apparently a well woman. The second case was similar. That patient also refused an operation. She was now no worse, and in some respects better, than she was some years ago.

Dr. Lusk thought great caution must be exercised in the performance of this operation. He did not condemn it, and had himself operated in four cases in which there was distinct evidence of disease of the tube, with good success.

Dr. E. W. Jenks, of Detroit, had seen several cases in which the operation had been performed without benefit. Where the ovaries and tubes were diseased there could be no question as to the propriety of its performance. In many of these cases of so-called hystero-epilepsy, which were often nothing more than hysteria, he considered the removal of the ovaries a positive wrong. The exploratory operation was not free from danger.

Dr. T. A. Reamy, of Cincinnati, said that a woman had been sent to him with dysmenorrhœa and hysterical symptoms, with the request that he should remove the ovaries. Five months' treatment of the cavity of the uterus, with change in the patient's surroundings and general treatment, resulted in entire recovery. He had seen several other striking cases. It was the exception to find the ovary healthy in women after the age of forty.

Dr. Emmet thought that the operation should never be done for dysmenorrhœa. He considered dysmenorrhœa a neuralgic condition, the result of anæmia. When dysmenorrhœa was relieved by the operation, it was because the general nutrition was improved by the removal of the ovaries.

Dr. Sutton agreed with Dr. Baker that where, in an exploratory operation, the ovaries and tubes were found to be healthy, they should not be removed.

Dr. Mann said that, although, as Dr. Emmet had stated, dysmenorrhœa was a neuralgic condition, he thought that that condition might become so firmly established that it could not be relieved without taking out the organ affected with the neuralgia. In two such cases he had thought the operation indicated. In one the patient was free from pain only three days of each month. He advised the operation, which was performed by Dr.

Clark, of Niagara Falls. The patient completely recovered. The second case was his own. The woman had suffered for a number of years with excruciating pain. The ovaries were enlarged and tender. The whole abdomen was tender. The ovaries were removed and the patient entirely recovered her health. He could not admit that there were no cases of ovarian dysmenorrhœa which could be relieved by the operation, but they were rare.

Dr. JOHNSON had not recommended the operation except under well-marked indications. He agreed with those who feared that the operation might be performed oftener than necessary. Its use in nervous and neuralgic conditions was not always so beneficial as in some other conditions, such as myoma of the uterus, for example.

(*To be concluded.*)

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of March 12, 1885.

The President, Dr. B. F. WESTBROOK, in the Chair;
Dr. A. H. P. LEUF, Secretary.

On the Use of Cocaine in Minor Surgery.—This was the title of a paper read by Dr. H. T. HALLECK. [See page 343.]

Dr. ARTHUR MATHEWSON remarked that it was in the room in which the meeting was held (in the Brooklyn Eye and Ear Hospital) that the first use of cocaine as an anæsthetic in the United States had been made. Dr. Noyes saw it for the first time in Germany, at the Heidelberg Congress; he also saw it privately demonstrated. The speaker had had Dr. Squibb make him a two-per-cent. solution of Merck's preparation, and it had proved very satisfactory—in fact, quite as effective as a four-per-cent. solution. The drug now prepared by Dr. Squibb was unexcelled. Some preparations caused a great deal of irritation at first, but this soon disappeared. The boric-acid preparation sent him by Dr. Squibb was the least irritating. Micrococci and bacilli formed in it, however, and it was almost impossible to prevent their formation. There was a difference in patients concerning the usefulness of this remedy—with some it did well, while with others it did not. As to its effect upon the lids, he referred to a case of cut lids that had been soaked with the solution previous to the operation, and the patient was anything but loud in its praise. It was usual to meet with failure in that class of cases. When he removed a cyst of the lid he cut from within (on the conjunctival side), pressed out the contents, and stirred up the interior with a small curette. The effect of cocaine on children operated upon for strabismus was quite striking; they were so very quiet.

Dr. R. G. ECCLES was reminded of hypnotism by some of the experiments with cocaine. A few years ago an American physician had made the same preparation, and called it erythroxyline hydrochloride. He left a specimen at the college with his thesis. The speaker had found cocaine satisfactory in parturition.

Dr. W. C. BURKE, Jr., had been told by Dr. Polk that he had been using it in a series of labor cases during the first stage. He injected it deep into the cervix and the surrounding connective tissue, with the result of causing a loss of sensibility in all the parts below the umbilicus, although pains in the back and the epigastrium persisted. The effect lasted from half to three quarters of an hour. It had no ill effect, and it did not influence dilatation. The speaker had used it before incising a pinhole os, previous to dilatation of the cervix, which was accomplished with very little pain, the patient only experiencing a "pulling feeling." He had employed the American product, and had found it irritate the eye for several minutes.

Dr. C. N. D. JONES thought it as important to report failures as successes in the use of new drugs. The medical journals contained very few reports of failures, but failures could be grouped and studied to advantage. He had used the drug wherever it was applicable. He had found it useful in laryngoscopy. In enucleation of the tonsil there was some pain, also at times in manipulations involving the urethra.

Dr. G. W. BRUSH had tried a fifteen-per-cent. solution, but with very little effect. His experience had been with Merck's and McKesson & Robbins's preparations.

Dr. LEUF said that the unsatisfactory results mentioned in the two cases reported by Dr. Halleck might be accounted for by the preparation used having been of inferior quality. He had subsequently employed it in two prepuce operations in children, and also in several eye cases, with satisfactory results. The drug acted decidedly as a hæmostatic, at least on small surfaces. In all recent cases he had used Merck's cocaine.

Epithelioma of the Eyelid removed by Applications of Benzol.—Dr. MATHEWSON reported the following history of a case: An Irish laborer, fifty years old, was first seen October 31, 1883, when he had a growth on the right lower lid, projecting two thirds of an inch, with an ulcerated surface. It had first been noticed, as a warty excrescence, a year or two before, and it had lately begun to grow rapidly. Microscopical examination, by Dr. W. H. Bates, showed it to be clearly an epithelioma. At first the treatment consisted in dusting the granulating surface with calomel; afterward (at the suggestion of Dr. Bates, who had records of two cases of epithelioma treated successfully, in his own practice, with the agent) in applications of benzol. After about three months' use of these remedies, applied three or four times a week, the growth had completely disappeared, leaving a smooth, depressed cicatrix. On the 1st of March, 1885, the man came back, with the history of a small ulcerating spot having appeared some six months before at the outer edge of the cicatrix. This was extending rapidly, but quickly began to contract under renewed applications of the same remedies, and was much reduced in size when the patient was presented at the April meeting of the New York Ophthalmological Society. On the 1st of May, when the patient left town, it was scarcely noticeable. On the 8th of July the man appeared again, with a considerable increase in the size of the ulcerating surface, but it had again yielded promptly to the applications. The benzol was brushed over the ulceration and the adjacent surface after they had been carefully wiped, and calomel was then dusted on. The applications were made from two to four times a week.

A case of necrosis of the tibia was presented by the PRESIDENT, and specimens of cystic kidney, calculous impaction of the bile-ducts, and renal calculus were shown by Dr. H. D. BLISS, and the histories of the cases related.

Meeting of March 26, 1885.

Acute Dysentery.—Dr. C. N. D. JONES showed a portion of the intestine of a lad, fourteen years old, who had died of acute dysentery occurring while he was under treatment for a fracture of the neck of the os brachii and a comminuted fracture of the shaft of the os femoris. The injury was received on the 7th of July, 1884, by his falling to the ground from a roof on which he was at work, and he was taken to the Brooklyn City Hospital. He did well until the 1st of August, when he complained of griping pains in the abdomen. There was tenderness on pressure, especially in the left iliac fossa. The next day diarrhœa came on, and soon passed into dysentery. Death took place on the 19th of August.

At the autopsy it was found that the fracture of the thigh had not united. The small intestine was somewhat congested,

but otherwise normal. The transverse and descending colon were contracted, and the entire colon and the rectum were thickened. Their mucous membrane was extensively ulcerated, the ulcers being largest and most numerous at the lower part. Instead of the intestinal tube being examined in the usual manner, by slitting it longitudinally with an enterotome, the colon was separated from the ileum, and a portion of the severed end was then rolled outward, and, a part of the gut being invaginated, a forcible stream of water was thrown into the sulcus thus formed on the peritoneal surface, with the result of rapidly producing complete inversion of the tube. The intestine was then inflated with air, and preserved in that condition.

Acute Rheumatism complicated with Suppurative Nephritis.—Dr. Isaac H. Platt read the notes of the case of an Irish servant girl, twenty-seven years old, who had been treated at St. Mary's Hospital, in the service of Dr. Kuhn. When she was admitted, on February 19th, she presented the typical symptoms of acute rheumatism, which followed the usual course for a period of nine days. On the 26th the temperature, which had been ranging from 103° to 105·5° F., fell to 102·5° in an hour under the influence of forty grains of antipyrine. The drug was then given in doses of thirty grains every four hours; the next afternoon the temperature had fallen to 101°, and the girl seemed better. The next day, however (the 28th), the temperature rose again to 104° despite the continued use of the drug, and in the evening she became actively delirious. The next day she passed into a typhoid condition, with low muttering delirium, subsultus tendinum, and carphologia. Careful examination was made for thoracic and abdominal complications, but none were found. The urine had been examined a few days before, and found free from albumin and sediment. Stimulating treatment was pushed to the utmost, but she gradually sank, the delirium persisting to the last, and died on the 3d of March. For two days before that time there had been no joint symptoms.

Report of the Autopsy, by Dr. Leuf.—Rigor mortis moderate, thirty-one hours after death. Lungs normal, except for collapsed portions in the right lower lobe, and less marked in the left lower lobe, together with several very hard pigmentary nodules of the size of a millet-seed. The heart was pale, soft, and flaccid, with all its cavities containing blood, mostly fluid, the little that was clotted being soft and friable. The liver was dark, and of normal consistence and vascularity. The pancreas was pale and soft. The left kidney was pale and soft, but otherwise normal. So was the right one, except in its upper third, which was dirty-yellow and rough externally. Thin, ill-conditioned pus and *débris* exuded from the cut renal pelvis. An abscess was found in the upper part of the organ, involving exactly the superior pyramid—no more and no less. The apex of the pyramid next below was also full of cheesy material that was breaking down and had a marked tubercular appearance. The uterus was congested, anteflexed, retroverted, and deflected to the right by the rectum, which was distended with gas. The endometrium was congested and exfoliating. The right ovary contained an old corpus luteum, about six mm. in diameter. Microscopical examination, by Dr. J. H. Hunt, showed numerous minute abscesses, but no tubercles.

Dr. Josephine A. Dupré had had some experience with rheumatism produced, in rabbits and dogs, by intra-peritoneal injections of lactic acid (two per cent.). One case resulted in endocarditis; two others in acute articular rheumatism; and four others in additional acute suppurations—in one case acute suppurative nephritis, in another several abscesses of the abdominal wall, in the third a pelvic abscess, and in the fourth an abscess of which she had forgotten the situation. The clinical histories of these cases were typical of acute inflammatory rheumatism, and the suppurative processes were demonstrated by post-mortem examination.

Cerebro-spinal Meningitis in a Roller-Skater.—Dr. George W. Cushing said that, about midnight of March 11, 1885, he had been called to see the patient (J. C.), who was twenty-eight years old and of fine muscular development. He was restless, with a hot, dry skin, the pulse 135, the temperature 104° F., the respiration labored, headache, and the pupils contracted and intolerant of light. He also had marked pharyngitis and bronchial congestion. He was averse to talking and to being disturbed. A febrifuge mixture was ordered, also bromide of potassium. Subsequently the man's wife gave the following history: Her husband had been engaged in a roller-skating match at the Madison Square Garden the week before, ending at midnight March 7th. He was at home the next day (Sunday), and rested a part of the time, but was unable to eat, and seemed very much exhausted. He went to New York on Monday, for the purpose of getting the money due him from the proceeds of the contest, and did not return until Tuesday, when he had symptoms of an ordinary "cold." The patient's surroundings were so poor that it was impracticable for all the speaker's directions to be carried out, and, when he called the next morning, he found that stupor was gradually setting in. There were urinary incontinence and spontaneous bloody evacuations from the bowels; there was also great difficulty in taking food and medicines, and the head was rigidly drawn back. The ankles and feet were swollen and chafed from the pressure of the skates. Cerebro-spinal meningitis was diagnosticated, and counter-irritants were applied to the spine and the back of the head, with cold to the top of the head. He continued to grow worse until the 15th, when the speaker was called in haste, and found him dead—he had probably been dead for several hours. The autopsy confirmed the diagnosis, the case having been placed in the Coroner's hands as a matter of public interest in connection with the present furor in regard to roller-skating.

Report of the Autopsy, by Dr. Leuf.—"The thoracic, abdominal, and cranial contents were examined by Dr. A. Warner Shepard, while it fell to my lot to examine and take notes of the spinal canal and cord. The body was of average height and build. The muscles of the lower extremities were rather well developed. There was very little fat. The left great toe was blistered inferiorly, internally, and superiorly, but the nail was not affected. The lungs were hypostatically congested behind and at the bases. The right lower lobe was collapsed at its anterior margin and posteriorly at the base. The heart was normal, except the usual eccentric hypertrophy found in athletes. The stomach was empty and tubular. The liver was normal, with the exception of some occasional fatty infiltrations. The spleen was a little larger than usual. The kidneys were healthy, but large; the right one was darker than the left. The bladder was so distended as to half fill the pelvis. The portal vein and its tributaries were distended with blood. The dura mater of the brain and cord presented nothing abnormal. The pia mater, however, was yellow, and about 3 mm. thick over the anterior half of the cerebral convexity on either side. All over this area the convolutions, including the upper two temporo-sphenoidal convolutions, were hidden from sight; but over the posterior half of the convexity the convolutions were distinctly discernible, and only the sulci were filled with pus. The inferior, or orbital, surfaces of the frontal lobes were deeply injected, but not purulent. The yellow thickening of the pia was also noticeable in the anterior half of the great median fissure of the brain, and extended half-way down to the corpus callosum. This purulent condition of the pia extended to the base of the brain, along the Sylvian fissure, to the interpeduncular space, where the same suppurative condition of the

pia was noticeable. That covering the pons and surrounding the medulla was affected in like manner. The intra-meningeal space of the cord was filled with pus to such an extent as to distend the dura, and well up in the incision made into the membrane in the lower part of the vertebral canal, preparatory to extracting the cord. The pia, throughout the whole length of the cord, was thick and yellow, while the cord itself was softened throughout its whole extent below the cervical enlargement. It was also sclerosed on the left side in the upper thoracic region, the white portion being principally affected."

In regard to the ætiology of the case, Dr. LEUF would differ with those gentlemen who would attribute the man's death to a healthful and beneficial exercise. That the prolonged mental and physical strain to which he had necessarily been subjected, together with the known privation and exposure, were important factors in bringing about the termination of the disease, no one could or would deny; yet it was wrong, he thought, to consider them the causes of the trouble. When we reflected how little there was in the way of precedent for such a supposition, in the face of extremely prolonged and excessive walking, running, rowing, swimming, and the like, it was fairer and more rational to infer that this meningeal inflammation had been brought about by a pre-existing cause. Still, the case might accomplish much good by checking the rage for roller-skating, although it was desirable that as many persons as possible should avail themselves of this graceful and harmless exercise within proper limits. Probably it should not be indulged in much more than half an hour at any one time. It was interesting to inquire how much work the craze was likely to bring to gynæcologists and to specialists in diseases of the chest, and perhaps to neurologists.

Meeting of April 9, 1885.

Exsection of the Upper Third of the Tibia.—Dr. GEORGE WACKERHAGEN read the notes of the case of a child, two years and a half old, who fell upon the pavement in May, 1884, and bruised the left knee. At first the injury seemed to be trifling, but a month later the part gradually became painful, red, and swollen. The services of a surgeon were not obtained until the 25th of September, when an opening was made just below the knee joint, which gave exit to a quantity of dark-colored blood slightly mixed with pus. After that the swelling disappeared, leaving a little opening just below the spine of the tibia, from which a small quantity of unhealthy pus was discharged daily. The speaker saw the child in consultation on the 15th of October, and found two sinuses leading to dead bone. At the operation, on the 19th, it was found advisable to remove the whole head of the tibia, together with about one third of the shaft, by subperiosteal exsection. The crucial ligaments were found to have been entirely destroyed, and the inter-condylar space was filled with unhealthy granulations. These were removed with a sharp curette, and the joint was thoroughly irrigated with a 1-to-2,000 solution of bichloride of mercury. A rubber drainage-tube was introduced into the joint, and the wound was packed with iodoform and bichloride gauze. No inflammatory reaction followed, and the temperature did not go above 99° F. The child had improved very much since the operation, and new bone had been produced from the periosteum. The knee could be flexed to an angle of about 45°, and extended as in the normal condition. Bauer's hip-joint instrument had been applied for the purpose of making continuous extension, and the shortening was not more than half an inch.

Gangrene of the Lower Extremity from Arterial Thrombosis.—Dr. F. A. JEWETT reported the case of a student, seventeen years of age, previously of good health, who had consulted him on the 30th of January, suffering apparently with a slight attack of intermittent fever. Several weeks before, he had indulged excessively in skating. Under the influence of quinine, he was soon able to be about the house. On the 4th of February, in the afternoon, he complained of pain in the back, but this had disappeared by the next morning, when, while dressing, he suddenly felt a numbness in both lower limbs, together with a "peculiar sensation" in the abdomen. He rapidly grew worse, so as to lose the powers of motion and sensation. By means of friction and a hot mustard bath sensation was restored to both extremities, but was soon lost again in the left leg. The speaker now arrived, and found the left leg blanched and cold below the knee, with loss of motion and sensation. There was little pain. The patient was placed in bed, and the limb was surrounded with hot bottles. The next morning there were ecchymotic spots on the lower third of the thigh and the leg and foot. On the 7th burning pains appeared in the knee and foot, and the temperature was 102·5° F. On the 6th of March, the line of demarkation having fully formed at the middle of the thigh, circular amputation was performed in the upper third, the incision coming within an inch of the healthy granulations. The femoral artery was found to be completely plugged, and the slight hæmorrhage which resulted came entirely from the smaller vessels. The patient died of shock two hours after the completion of the operation. In disguising the odor of the gangrenous parts, at the time of the operation, the best result was obtained with nascent chloride of lead, made by adding a drachm of aqueous solution of nitrate of lead to a pailful of solution of salt.

Autopsy, by Dr. Leuf.—The kidney connective tissue was markedly increased. The spleen was enlarged, and contained buff-colored spots. The liver was slightly fatty. A clot was found in the abdominal aorta, about four cm. above its bifurcation and extending down into the two common iliacs. It only partly filled the aorta and the right common, external, and internal iliacs, so that some blood had been admitted through these vessels to the parts below; but the left common, external, and internal iliacs were solidly and perfectly plugged with a firm thrombus adherent to their walls. This plug extended down into the femoral as far as the end of the stump, where it had been cut off during the operation. The plug fitted the vessel somewhat loosely below the lower part of the external iliac. The collateral circulation probably took place through the deep circumflex iliac and the lumbar arteries.

Gangrene of the Leg due to Popliteal Embolism.—Dr. LEUF related the case of a German midwife, about thirty-five years old, who had had rheumatism at times for fourteen years, also frequent attacks of dyspnœa due to cardiac valvular disease. The attack of rheumatism which terminated her life began in the latter part of April, and at that time she was attended by another physician. She had the ordinary symptoms of rheumatism, and presented inflammatory signs in both ankles. After some days' treatment the feet became better, and the physician had a pack of ice-water and salt applied to the left foot. This was continued under protest for upward of two hours and then removed. A few hours later the patient felt a sensation as of something darting down the left thigh, along the course of the femoral, and stopping with a sudden jar at the back of the knee. This sudden jar was a shock to her whole body, and caused the entire leg below the knee to feel as if suddenly electrified, and the leg had continued numb, with tingling sensations, from that time until the speaker was called in, two days later. The other physician could not be induced to pay any attention to these symptoms, or even look at the foot. The speaker found the foot cold and swollen, with the plantar surface of a dark hue. The sensibility of the foot was impaired, and it could hardly be moved. The patient complained of severe pains in the toes and

instep. Her pulse was very irregular and her heart feeble, with mitral stenotic and regurgitant murmurs well marked. Her face wore an anxious, expectant expression, and was of a leaden pallor. She had black hair and a dark complexion. Examination at the back of the knee revealed a rod-like body beneath the skin in the popliteal space, having a diameter of over 1 cm. This hardness extended almost the whole length of the popliteal space. The diagnosis was made at once of embolism of the popliteal artery, from the lodgment of a detached heart thrombus caused by valvular disease the result of acute inflammatory rheumatism. The treatment consisted in giving opium and *Cannabis indica* to relieve pain and mental depression; digitalis to strengthen the heart; *Cascara sagrada* and extract of malt to relieve constipation and promote a flagging appetite; wine to hasten reaction; and a good nutritious diet to maintain and increase her strength. The speaker's prognosis was gloomy, and he predicted gangrene of the left foot and leg. He considered it dangerous to operate, because of the patient's condition and the irregular action of her heart, and believed she had the best chances of recovery by patiently awaiting spontaneous amputation. Hot applications were made to the foot and leg. Her general health continued good, and she ate abundantly. The pain grew very much worse, so that she was not freed from it even by taking a grain of opium every hour almost continuously for days. The foot became darker, and the toes black and dry. Dark-red patches made their appearance about the ankle, and gradually extended up the leg almost to the knee, from which point they receded about 4 cm. and began to form a line of demarkation. This line was dentate, so as to form two side flaps if spontaneous amputation occurred. Dr. B. F. Westbrook was called in consultation by the speaker, and fully coincided with him in regard to the case. A few blebs formed on the foot and ankle, and afterward on the leg, exuding a semigelatinous, sero-sanguineous fluid. The stench was considerable, but it was easily controlled with carbolic acid and biehloride-of-mercury solution. On the 29th (twenty-four days from the time he first saw her) the speaker found the patient sitting up, panting for air, with all the signs of orthopnœa. Mucous râles could be distinctly heard without applying the ear to the chest. After consultation, and taking her preceding history into consideration, he concluded that she had a pulmonary infarction and œdema of the lungs. It was Sunday, so that no oxygen could be obtained; and large doses of chloride of ammonium were prescribed. The next day she was found in a dying condition. An autopsy was not allowed.

There had seemed every reason to believe that, had it not been for the unforeseen accident, her strength would be sufficient to carry her through the process of spontaneous amputation. Her heart's action was so irregular and incompetent that she would have been very likely to succumb to an anæsthetic. Taking into consideration the general results of cases of gangrene, we learned that the majority of the patients operated upon died, and death was often hastened by the shock of the procedure. It seemed to the speaker that a large proportion of patients would fare better with nature than with the surgeon; nevertheless, the reverse was true of many others. He felt certain, therefore, that, by a more careful selection of cases with reference to the advisability of operating, a much larger percentage of recoveries would result.

The two cases of gangrene being under discussion, Dr. Leuf remarked that, after careful consideration, he was disposed to ascribe a spinal origin to the thrombus in the first case, on the supposition that a special myelitis might set up nutritive changes in the coats of the aorta, and these in turn give rise to the thrombus. He thought this the best way to account for the formation of the plug. The excessive exercise of both lower extremities might be sufficient cause for the inflammation of the cord.

Dr. C. N. D. Jones thought the fever symptoms would have been interesting as bearing upon the question of whether the primary cause was a myelitis or an arteritis. He wished to know if there had been any syphilis.

Dr. Jewett replied that the case began with chills and fever on a Wednesday; there were no chills the day before, but there had been some on the preceding Monday. He did not see the patient on Thursday, but saw him afterward, when he was without fever. No syphilitic history could be obtained; if there was any syphilis, it must have been hereditary. The patient only complained of numbness of the left thigh. In Simpson's works mention was made of an obstetrical case almost parallel. The plug was about 2·5 cm. above the bifurcation, and the symptoms were about the same. The connection between the cord and the thrombosis that had been suggested was not very clear to him, and seemed a little strained. He also thought it questionable if excessive exercise was the cause of the trouble.

Dr. Leuf rejoined that the lack of much pain in Dr. Jewett's case would support the myelitis theory.

The President thought it rather curious that selerosis and softening should have taken place, as it would appear in this case, with hardly any symptoms. He asked if the patient had been skating shortly before the onset of the sickness.

Dr. Jewett answered, "A few days before."

The President added that it was also curious to see interstitial nephritis in one so young. This kidney trouble and cord affection were sometimes associated. Perhaps this case was one of embolism, and not of thrombosis.

Dr. Jewett said that there was no post-mortem evidence of any possibility of embolism.

The President asked if the plug, extending so far down as it did, would not prevent the collateral circulation suggested by Dr. Leuf.

Dr. Leuf explained that the plug fitted the vessels loosely from a point in the external iliac about 2 cm. above the iliopubic ligament.

The President, in reply to a question as to the advisability of an operation in Dr. Leuf's case, said that it was absolutely contra-indicated by the gross incompetence of the heart.

Miscellany.

The International Medical Congress.—The "Maryland Medical Journal" comments as follows on the recent work of the American Medical Association's new committee:

"We present in another column a partial report of the new committee on the Congress, which held its meeting in New York city on September 3d. We invite attention to the recent work of this committee, and would urge our readers to compare this work with that of the first Committee on the Organization of the Ninth International Medical Congress, which was published in the number of this Journal of April 4, 1885. We will attempt, in a brief way, to show by way of comparison that the new committee has played its part in this affair in a manner in thorough accord with what might have been expected of it. This committee should never have had an existence in the first place. It has failed to do anything save provoke strife and differences in the profession in this country, and this last attempt to organize the preliminary arrangements for the Congress is but the crowning act of its incapacity and unfitness for the work it has undertaken. The committee was called into existence by a small faction of sore-heads at New Orleans, which introduced false and absurd issues into the plan of or-

ganization of the Congress, with no purpose of promoting the welfare and scientific work of the Congress, but simply to make prominent certain private grievances and petit ambitions. The agitators of this rebellious movement against the work of the first committee were chiefly men who failed to receive appointments in the organization of the Congress.

"In order to overthrow the work of the first committee the cry of the 'code' was raised, and sectional feelings were appealed to. The work of disorganization was in this wise inaugurated. We ask every impartial mind, What does this mean? In what way have the fortunes of the Congress been benefited by the work of the new committee? Will any one venture to assert that the Congress can be a success under the arrangement now proposed? We will endeavor to answer these propositions.

"First, we will call attention to the fact that the new committee has virtually thrown aside the 'code' issue. It has thrown open the doors of the Congress to all members of the regular profession of medicine in this and other countries, with no restrictions other than the simple inscription of their names on the register, and taking out of tickets of admission. The committee does not undertake to say who are members of the regular profession. This plan is the one proposed by the first committee, but not the one proposed by the new committee at the Chicago meeting, which forced a large number of the first appointees to present their resignations. In short, this new committee has accepted the work of the first committee after having driven out of the organization of the Congress a large number of the most distinguished members of the profession in this country. By introducing the absurd 'code' issue at Chicago, the committee has completely alienated from the organization of the Congress the very best scientific minds. It has rescinded its destructive work at Chicago in the face of the adverse criticism of the almost entire medical press in this country and in Europe, but not until after it had succeeded in filling a number of its appointments with men of second-rate merit. The committee adopts the 'code' issue in this respect only. It has made no appointments except with 'old-code' adherents. The present organization, therefore, will only be represented by 'old-code' men. In order to carry out the 'code' idea and the 'sectional' idea, the committee has filled the various offices of the Congress with men, a few of whom are scarcely known at home or abroad, and whose fitness for the positions to which they have been called may be regarded as of questionable character.

"Second, we direct attention to the fact that the rules for the government of the Congress are almost identical with those framed by the first committee. The first committee created nineteen sections, whereas the present arrangement provides for only seventeen; but this change has been brought about in this manner. The Section on Medical Education, Legislation, etc., has been dropped and the Section on Otology has been added to the Section on Laryngology. A number of verbal alterations were introduced into the rules adopted by the new committee, but the general purport of these rules is the same as adopted by the first committee.

"The only reformation made by the committee in the plan and organization adopted by the first committee is reduced to this: 'new-code' men have been dropped and 'old-code' men have been substituted for them. The changes in the *personnel* of the presidents of sections are thus shown. In the Section on Anatomy, W. H. Pancoast, of Philadelphia, has been substituted for Joseph Leidy, of Philadelphia; Section on General Surgery, William T. Briggs, of Nashville, for D. W. Yandell, of Louisville; Section on Medicine, A. B. Arnold, of Baltimore, for J. M. Da Costa, of Philadelphia; Section on Obstetrics, DeLaskie Miller (residence not known to us) for T. A. Reamy, of Cincinnati; Section on Therapeutics, etc., F. H. Tirrell (residence not known to us) for H. C. Wood, of Philadelphia; Section on Military and Naval Surgery, Henry F. Smith for David L. Huntington, U. S. A.; Section on Pathology, E. O. Shakespeare, of Philadelphia, for Francis Delafield, of New York; Section on Diseases of Children, J. Lewis Smith, of New York city, for Abraham Jacobi, of New York; Section on Ophthalmology, J. W. Calhoun (residence not known to us) for Henry D. Noyes, of New York city; Section on Otology and Laryngology, S. J. Jones, of Chicago, for Clarence J. Blake, of Boston, on Otology, and George M. Lefferts, of New York city, on Laryngology; Section on Dermatology and Syphilis, A. R. Robinson, of New York city, for William A. Hardaway, of St. Louis; Section on Public and International Hygiene, Joseph Jones, of New Orleans, for Hosmer A. Johnson, of Chicago; Section on Collective Investigation, etc., Henry O. Marcy, of Boston, for N. S. Davis, of Chicago; Section on Psychological Medicine, John P. Gray, of Utica, N. Y., for S. Weir Mitchell, of Philadelphia.

"It will thus be observed that the changes made by the committee in the appointees of the Congress are not of a character to inspire the very highest order of scientific work, nor do we believe that the Congress as now organized will attract that attention and interest it would have received under the plan of organization first proposed. The revolutionary work of the American Medical Association, in authorizing the changes made by its committee, is entitled to every atom of criticism and censure it has received. There was no reason or justice in its action. This action will have but one result, that of lowering the standard of scientific work in this country and of introducing into the ranks of the profession an element of discord and disturbance which can not be effaced during the next generation. The association has given its entire influence toward elevating the claims of men who care more for their own advancement than for the general professional good. It has favored an alliance with ideas and principles which have no existence in the scientific creed of our times. The present organization of the Congress, as far as it is known, bears no comparison in point of ability and authority to the first organization. Inasmuch as it has been called into existence out of deference to false issues and demagogical ideas, its results will not only prove highly prejudicial to the success of the Congress, but can have only an unfavorable influence upon the status of the profession in the United States."

The "Medical Record" says:

"For the first time in its history the International Medical Congress has fallen into the sole management of a society of the country in which it is to meet. Although Sir James Paget, an ex-president, expressly affirms that this was not expected or desired when an invitation was given, yet it is evident from recent events that the society referred to intends to retain its hold and force upon the Congress its own men and methods. The work of the committee which met here in such secrecy on September 3d but too surely confirms this. Details of its mysterious labors are given elsewhere. These show some indications of adroit wriggling to escape the results of previous blunders, but no manly meeting of the issues, and no recognition of the real demands of the profession. The committee have utterly eliminated and blotted out Drs. Cole and Shoemaker, trusting, we presume, to gain back Philadelphia by thus making scapegoats of these gentlemen. They have also filled the vacancies in the presidencies of the sections. Their list of names suggests both freshness and decay, but does not fairly represent American medicine. And the profession will very quickly ask who many of these new men are who thus take the seats which have heretofore been held only by recognized leaders. Is our country to be made ridiculous by their upheaval, and the Congress turned into a menagerie of unknown doctors and ethical sticklers?

"However, though the appointments are weak enough, they need not kill the Congress. But a much more serious thing remains: no attempt was made to remove the code issue from the Congress. It is still incumbent on an American physician to subscribe to the American Medical Association's Code of Ethics in order to hold any official position in the Ninth International Congress—if it meets in this country. The stupidity, as well as absolute wrongfulness, of failing to meet this point is certainly beyond parallel. The good Lord only knows, perhaps, what a number of nice, venerable, determined old gentlemen we have here trying to manage our little medical world; but many of us are getting some inkling of their immeasurable and fathomless fatuity. It appears, at any rate, that they are bound to destroy the Congress, for they persist in forcing upon it restrictions which cut off from the Congress and impugn the respectability of a large number of the most honored men in our profession. In thus doing they violate justice and right, break the pledges at Copenhagen, and affront their fellow-physicians here. Of course a bitter controversy is inevitable; and we are sorrowfully forced to the conclusion that there is at present no hope for the Congress whatever. The profession here and in other centers

is almost a unit against the policy of the association and its committee, and it will continue to protest against the organization of a meeting which will be so thoroughly misrepresentative of American medicine."

In another article the "Record" says:

"The real trouble in the case of the Washington Congress is that, under the direction of a few gentlemen prominently interested in the American Medical Association, the local issue of the code has been forced upon an international scientific body. There was no justice or right in this, and it was in violation of all precedent and of tacit pledges made at Copenhagen. The consequence of their action is that a large number of our country's best physicians are incapacitated from holding any position in the meeting, and, of course, can not with self-respect take part in the work of a body which impugns their professional respectability. The profession has almost unanimously condemned this action. In proof of this we give here a list, which we believe is complete, of the journals in this country that have disapproved of the course of the association: *New York Medical Journal*, *Boston Medical and Surgical Journal*, *The Medical Record*, *Chicago Journal and Examiner*, *Maryland Medical Journal*, *Medical Age*, *Philadelphia Medical Times*, *Louisville Medical News*, *Atlanta Medical and Surgical Journal*, *Virginia Medical Monthly*, *Indiana Medical Journal*, *Pacific Medical and Surgical Journal*, *American Practitioner*, *New Orleans Medical and Surgical Journal*, *Cincinnati Medical Journal*, *Columbus Medical Journal*, *Medical News*, *Kansas City Medical Index*.

"We believe that there is not one of the few medical journals that defend the course of the present committee which has not some official or close personal connection with the organization of the American Medical Association and the Congress.

"There can thus be no doubt as to the sentiments of the profession. It is impossible that this sentiment should be changed by the mere fact that Drs. Cole and Shoemaker have been so completely effaced. This was a sop to the Philadelphia Cerberus; but it was a mean act and will win no support to the committee."

The "Medical News" publishes the following:

"At the stated meeting of the Luzerne County Medical Society, held at Wilkesbarre on Wednesday, September 9th, the following resolutions, offered by Drs. Mayer and Guthrie, were discussed and then carried, but one vote being recorded in the negative:

"*Whereas*, The International Medical Congress is a scientific body taking no cognizance of medical ethics or politics, therefore be it

"*Resolved*, That it is the sense of the Luzerne County Medical Society that the officers and members of the Medical Congress should be the most eminent representatives of the entire regular profession of our country without regard to their views as to extraneous subjects.

"*Resolved*, That the action of our brethren of Philadelphia, and of other cities, in declining to hold office in connection with the said Congress as now proposed to be organized, and in protesting against the method of its organization, is hereby heartily approved.

"In seconding the motion for the acceptance of the preamble and resolutions offered by Dr. Guthrie, Dr. Mayer said:

"I desire to state that I had intended presenting to you to-day other resolutions of similar tenor, but, upon learning of Dr. Guthrie's purpose, will content myself with endeavoring to further the passage of these, which I so highly approve.

"This whole matter referred to in the resolutions, when compressed into a nutshell, would seem to be as follows: That the committee of our National Association, originally appointed to secure a proper representation of delegates and committees for the coming International Congress, made selections which gave satisfaction to the best professional judgment of our country; that then certain aspiring and neglected members of the association conspired at the last moment to exclude from the appointed list a large number of men favorably known abroad and distinguished at home for their zeal and success in scientific labors, upon the plea that these gentlemen differed from the majority of the association about ethical matters, well the subjects of legitimate controversy. They succeeded in their plot, and in the enforced substitution for many honored names of others comparatively obscure. This action has caused a profound sensation in medical circles, and has aroused the best sentiment of the country in opposition to this usurpation. A large number of the ablest, the purest, and also the most conservative members of our profession, including, near at hand, such lights as D. Hayes Agnew, Bartholow, Stillé, Leidy, Mitchell, and Pepper, and at a distance other prominent men in New York, Boston, Baltimore, the South and the West, have combined in a protest against this action of the Modified Committee, and have declined to fill the positions assigned to them unless the original status of things be restored. In the mean time some of the members of this committee are inundating the land with proclamation and manifesto, and are endeavoring, by public circular and private solicitation, to whip and spur county societies and individual members into adherence to their views.

"I trust that our society will now speak 'with no uncertain sound' and place its stamp of reprobation upon this despotic attempt of a few to coerce the many, and, by a unanimous vote, confirm the manly protest made by our distinguished brethren in behalf of all that is broad, high-toned, liberal, and free in American medicine. Its name has been soiled in the dust of corrupt medical politics. Let us do our little to help cleanse it."

The Chicago correspondent of the "Boston Medical and Surgical Journal" writes:

"The International Congress, from the standpoint of the profession here, has a gloomy outlook. We can not see how from the present situation the gathering can be in any sense international. There may be a large meeting, but if only American doctors attend, and if, as the prospect is certain, many of the most distinguished members of our own profession are absent, what is the use of a Congress at all! Drs. Lyman, Hyde, Jackson, Parkes, and Senn have publicly announced that under the present organization they *could not* serve in the positions to which they have been appointed. Not only have a large number of the strongest men in the country declined to participate, but so large a class that the idea is growing among the profession here that the Congress will not be worth attending, that it is a foredoomed failure as an international gathering. This feeling is heightened by the indications from abroad of a growing sentiment of dissatisfaction with our ways of doing, which is entertained by the profession of Europe, and which promises to reduce to zero the small delegation of eminent visitors we had any reason to expect under the most favorable auspices.

"And the present prospects promise little for the amelioration of the situation. We can see how some of the difficulties would disappear if one side or the other would back down—a performance there is not the smallest chance of our seeing. The leaders of the association movement and the company of decliners to serve both belong to that class of mankind who do not retreat easily; they will not do it in this instance. And even if they did, and mutually did, the injury done in Europe to the prospects of the Congress are past repair. The spectacle is a humiliating one for the American profession."

The "Western Medical Reporter" says:

"Our readers may have noticed in former issues of the 'Reporter' a conspicuous absence of comments upon the war-cloud which now obscures the bright horizon that erstwhile encircled the coming International Medical Congress. We assure our readers that our silence has not been due to indifference upon our part, for the matter is certainly one of vital importance to every medical man of a progressive mind. There seemed, however, to be no probability that the prominent gentlemen who are most closely identified with the best interests of the American medical profession would so far forget themselves, and that spirit of liberality and scientific progress which has been pre-eminently the claim of the profession of the United States, as to seriously embroil themselves in a quarrel that could but engender the contempt of the majority of the profession both at home and abroad; we now, however, appreciate our mistake. To open the closet and exhibit to the world the skeleton of the American medical family, 'the code,' was indeed in very poor taste to say the least, especially when such an exhibition was absolutely certain to prove prejudicial to the coming Congress. It seems a trifle peculiar that we Americans, with all our boasted liberality and freedom of thought, should be the first to cast a stone at the medical freethinker, and it may well seem a trifle paradoxical to the scientific representatives of what we are prone to term the effete governments of the Old World to find the future of the International Congress endangered by the intolerance of American physicians.

"Our European brethren may perhaps appreciate the fact that the

American Medical Association in its action regarding the Congress has not voiced the sentiments of either the majority or the best of the members of the profession in America, but we are none the less disgraced in their opinion. It is perhaps wrong to lay this trouble at the door of the association as a whole, for, as in every other organization of a similar character, it will be found that the active management is in the hands of a very few individuals; but, as the matter now stands, there is nothing else to bear the responsibility of the family quarrel. With all respect to its venerable editor, the 'Journal of the American Medical Association' appears to be the only obstacle in the way of an amicable rearrangement of the committees and a resumption of the strictly scientific work which, if undisturbed, will make the coming Congress fully as successful as any of those which have preceded it. Pertinacity is an excellent quality under exceptional circumstances, but in the present instance concessions for harmony's sake would be in much better taste. The time is past for a body of men, scientific or otherwise, to attempt to forcibly coerce the opinions of the majority, and experience has taught the profession within a very few years that the code question had better be left to take care of itself.

"The physician's own conscience is his most trustworthy mentor. He may, from that purest of motives, honesty, decline to consult with one whose views are so dogmatic and so diametrically opposed to the results of scientific research that there could not possibly be any interchange of ideas which would be liable to redound to the patient's advantage. To accept a fee for such a consultation would be akin to larceny. To consult with a man who meets a consultant, not as a '-path' or an '-ic,' but as a respectable physician, is, however, above reproach, whether both are recognized by the association or not. The propriety of a consultation ought to be determined by the characteristics of the men and not by the school which has empowered them to practice. The relation of a certain proportion of physicians to the mass of the profession is a trifle like the old story of the pigs in the clover patch. They have protected themselves by a barbed-wire fence denominated 'the code,' that plainly says to the fellows upon the outside, 'Thou shalt not steal.' The favored ones have always seemed to be strangely familiar with the spaces between the wires, and, in case their less fortunate brethren should find a few plums upon their side of the fence, they have always been perfectly willing and eager to rush out and help themselves; now, however, that the outsiders have shown themselves both able and willing to jump clear over the wires, the protest of the fat fellows is most vehement. It is a singular fact that the young man who graduates at a reputable college and settles down in a new locality to earn his bread and butter will meet with less courtesy and more bitter opposition at the hands of the gray-haired adherents of ye venerable code than at the hands of the 'irregulars.' We have known instances in which the aspirant to medical fame has had his first cold-water bath at the hands of men whose names he had been previously proud to read upon his diploma.

"How long the profession will continue to depreciate itself in the eyes of the public by unseemly strife is a question, but the millennium is devoutly to be prayed for. The explanation of the fact that the medical profession commands so little respect at the hands both of the laity and various municipalities is simply that its members are continually employed in cutting each other's throats. They are expected to labor for nothing—or what is worse, glory—and to devote themselves to the welfare of a thankless public simply because there is not among them sufficient professional *esprit de corps* to encourage them to battle for their rights. Should a surgeon refuse to work for the State, city, or any private corporation for nothing, or, at most, for a mere pittance, there are a thousand others who will jump at the chance if offered them. Doctors do sometimes refuse to accept glory from conscientious motives, as is illustrated by the resignation of so many gentlemen whose names graced the committees for the coming Congress. As our respected contemporary, the 'Medical Age,' has aptly remarked, 'even the Michigan men have resigned their exalted positions upon the committees, and when a Michigan man resigns an office there must be something rotten in Denmark.' If the statement had been a trifle more comprehensive, and had embraced the profession as a whole, it would have been quite appropriate. There is no one, however, who is better qualified to express an opinion regarding the Wolverines than the editor of the 'Age.' We will live in the hope that the cement of brotherly love will be spread on hot and thick at the St. Louis meeting next year, and that certain prominent members of the association may become quite expert in the use of the trowel by that time. We fear, however, that there will be no peaceful interim in which to practice the new and to them novel exercise. There are others, too, who might find profitable employment in professional tailoring in order that our poor skeleton, the code, may be provided with garments new wherewith to cover his unseemly nakedness, in case the profession is bound to trot him out for the edification of the scientific world at the next meeting of the association."

The Erie County Midwifery Law, passed at the last session of the Legislature, reads as follows:

"SECTION 1. On or before the first day of July, eighteen hundred and eighty-five, the county judge of Erie County shall, by an order to be filed in the Erie County Clerk's Office, appoint a board of examiners in midwifery to consist of five members who shall have been licensed to practice physic and surgery in this State, and thereafter, as often as any vacancy shall occur in said board, said county judge shall, by a like order, fill such vacancy.

"SEC. 2. Immediately after the filing of said order said board shall organize by the selection of one of its members as president, and of another as secretary and treasurer, who shall hold their office for one year, and be thereafter annually elected, and shall adopt and have power to adopt and enforce such rules and regulations as are necessary to carry out the purposes and provisions of this act.

"SEC. 3. Such examiners shall meet on the first Tuesdays of October and April in each year, and on such other days as such board may appoint, in the city of Buffalo, after due notice thereof is publicly given, and shall then examine all candidates of the age of twenty-one years and upward, possessed of good moral character, who shall present themselves to be examined for license to practice midwifery in the county of Erie, and shall, on receipt of ten dollars, issue their certificate to any person so examined who shall be found by them to be qualified, which certificate shall set forth that said board has found the person to whom it is issued qualified to practice midwifery, and shall be recorded by the clerk of the county of Erie in a book to be kept by him for that purpose. All moneys going into the treasury of this board shall be applied to defray the expenses of this board.

"SEC. 4. Any person who has received and recorded such certificate shall thereupon be designated a midwife, and authorized and entitled within the county of Erie to practice midwifery in cases of normal labor, and in no others; but such persons shall not in any case of labor use instruments of any kind, nor assist labor by any artificial, forcible, or mechanical means, nor perform any version nor attempt to remove adherent placenta, nor administer, prescribe, advise, or employ any poisonous or dangerous drug, herb, or medicine, nor attempt the treatment of disease, except where the attendance of a physician can not be speedily procured, and in such cases such persons shall at once, and in the most speedy way, procure the attendance of a physician.

"SEC. 5. Said board of examiners shall have power, on proper cause shown and after hearing the person holding their certificate, to recommend to the county judge of Erie County the revocation of the same, and said judge shall have power to revoke such certificate and license.

"SEC. 6. Any person who shall practice or, without the attendance of a physician where one can be procured, attend a case of midwifery or obstetrics within the county of Erie after the thirty-first day of December, eighteen hundred and eighty-five, without being duly authorized so to do under existing laws of this State, or without having received and recorded the certificate provided for by this act, and any person who shall violate any of the provisions of this act, shall be guilty of a misdemeanor, and, on conviction thereof, shall be fined not less than fifty dollars nor more than one hundred dollars, and shall forfeit any certificate theretofore granted under the provision of this act.

"SEC. 7. This act shall take effect immediately."

The first meeting of the board (consisting of Dr. M. D. Mann, president, Dr. J. H. Pryor, secretary, Dr. H. R. Hopkins, Dr. P. W. Van Peyma, and Dr. J. W. Keene) for the purpose of examining candidates

will be held Tuesday, October 6th, between the hours of 3.30 and 6 P. M., at the Fitch Institute. If necessary, the board will meet on other days, which will be announced. Any person applying for examination must furnish satisfactory evidence that she is of good moral character, twenty-one years of age, or more, and has attended, or assisted in attending, ten or more cases of labor. The examination will be both written and oral, and the answers to questions must be written or spoken, as the board may direct. Applicants will be examined in English or German, as they may desire. It will be the aim of the board to determine whether a candidate is competent to fulfill the requirements and instructions of the law as stated in Sections 3 and 4, and the character and scope of the examination will be planned with that intention. The candidate must possess a knowledge of the following essential subjects: The structure of the external and internal parts of the female generative organs and pelvis. The symptoms, mechanism, course, and management of natural labor. The symptoms and indications of complicated or abnormal labor, and the emergencies which render it necessary to seek a physician's advice. How to care for the mother and child after the child is born. The hygiene of the sick-room, including cleanliness, etc. The prevention of disease, and how to avoid infection and contagion.

Further information can be obtained by applying to the secretary, J. H. Pryor, M. D., 327 Franklin Street, Buffalo.

The French Society of Otology and Laryngology, as we learn from the "Union médicale," will meet in Paris on the 8th, 9th, and 10th of October.

Preservative Solutions for Embalming.—Santer (quoted in "Union médicale") recommends, for temporary use, injecting the vessels with the following solution:

Carbolic acid	1 part;
Glycerin	10 parts;
Alcohol	5 "
Water	40 "

If permanent preservation is desired, this is to be followed by a copious injection of a one-to-two solution of chloride of zinc colored with fuchsin, or of a solution (strength not stated) of sulphate of albumin [? aluminium] colored with cochineal. The surface of the body is then to be coated with vaseline or with a sandarac varnish containing carbolic acid, the cavities being filled with cotton treated with corrosive sublimate or soaked in a five-per-cent. glycerin solution of carbolic acid.

The Leuval Prize for an Improved Instrument for Deafness.—Baron Léon de Leuval, of Nice, has offered, through the Third International Congress for Otology, a prize of 3,000 francs for the best portable instrument, constructed on the principle of the microphore, for the improvement of hearing in cases of partial deafness. Instruments intended for competition must be sent before December 31, 1887, to one of the members of the jury appointed to decide upon their merits. The jury consists of Prof. Hagenbach-Bischoff, Ph. D., M. D., chairman of the jury, Basle (Missionsstr. 20); Benni, M. D., Warsaw (16 Bracka); Prof. Burckhardt-Merian, M. D., Basle (42 Albanvorstadt); Gellé, M. D., Paris (49 Rue Boulard); Prof. Adam Politzer, M. D., Vienna (I Gonzagagasse 19). Perfected instruments only are to be considered, and with reference particularly to their mechanical construction, the proper application of the laws of physics and their power to improve the hearing. The prize will be awarded at the Fourth International Congress for Otology, to be held in Brussels in September, 1888. If none of the instruments presented are considered worthy of the prize, the competition will be kept open until the meeting of the Fifth Congress.

Companion for an Invalid.—An English lady, of extensive experience in the care of the sick, writes us that she is desirous of obtaining a position as traveling companion to an invalid, and that she is willing to come to America for the purpose of accompanying such an one back to Europe. We shall be happy to furnish her address to any of our readers who may wish to secure her services.

The American Public Health Association will hold its thirteenth annual meeting in Washington, D. C., December 8, 1885. The Local Committee intrusted with perfecting arrangements for the meeting, which includes transportation and entertainment for the members of the association and place for holding the sessions, is as follows: Dr. Smith Townshend, chairman; Dr. J. C. McGinn, secretary; Dr. J. S. Billings, U. S. A.; Dr. John M. Brown, U. S. N.; Mr. William P. Dunwoody, National Board of Health; Hon. John Eaton, Sr., Prof. John Gamgee, Dr. A. Y. P. Garnett, Dr. A. L. Gihon, U. S. N.; Dr. Walter Gwynn, Dr. Charles H. H. Hall, U. S. N.; Dr. C. G. Hirndon, U. S. N.; Dr. Adrian Hudson, U. S. N.; Mr. E. S. Hutchinson, Dr. J. H. Kidder, U. S. N.; Dr. William Lee, Dr. George B. Loring, Dr. De Witt C. Patterson, Dr. Stephen O. Richey, Dr. Charles Smart, U. S. A.; Dr. Thomas J. Turner, U. S. N.; Dr. J. M. Toner, Dr. P. S. Wales, U. S. N.; Dr. Ralph Walsh, Dr. Charles H. White, Dr. T. S. Verdi, Mr. Samuel A. Robinson, and Dr. D. E. Salmon.

Extract of Pinus Canadensis.—Dr. C. H. Davis, of Tunkhannock, Pa., writes to the Rio Chemical Company as follows:

"I can speak positively of the great value of Kennedy's extract of pinus canadensis. I have been treating a case of protruding piles of twenty years' standing, making life almost intolerable at times; they have been treated for years with only palliative results. About a year ago an operation was submitted to, since which time the tumors have remained smaller and less sensitive, but a new trouble soon set in, namely, itching to a terrible extent, which nothing seemed to relieve until I tried the extract of canadensis, two parts to one of glycerin, two or three applications of which relieved the itching entirely, and the disease is being rapidly benefited in every way. Have used it only once a day after each evacuation. I find it an excellent remedy in leucorrhœa also."

THERAPEUTICAL NOTES.

The Physiological Action of Hydrastis Canadensis.—Fellner ("Med. Jahrb."; "Ctrbl. f. Gynäk.") has found, by experiments on dogs and rabbits that golden seal gives rise to changes in the blood-pressure and in the action of the heart. Increase of the blood-pressure arises chiefly from contractions in the vascular system, and its decrease from paralysis of the vaso-motor centers, dilatation of the vessels, and retardation of the pulse. The depressor nerve has no influence upon a diminution of the blood-pressure induced by hydrastis, although in the vascular areas of the splanchnic and other nerves contractions and dilatations occur. If large and then small doses are injected while the aorta is compressed above the diaphragm, the pulse is alternately retarded and accelerated; and this is followed by tumultuous action of the heart and its exhaustion and paralysis. The action of hydrastis, whether irritative or paralyzing, is not confined to the vaso-motor nerve centers, but it acts also upon the cardiac ganglia; it is therefore a cardiac as well as a vascular poison. The drug acts upon the muscular tissue of the uterus as it does upon the blood-vessels, causing contraction and relaxation. In certain cases this action may be observed even in the small intestine. From one to two drops of a ten-per-cent. solution of hydrochlorate of hydrastine, injected subcutaneously, give rise to energetic uterine contractions. According to the author, this salt and phosphate of berberine should be used in practice, as, in small doses, they exert the same action as the fluid extract of *Hydrastis canadensis*.

Capsicum in the Treatment of Delirium Tremens is no novelty, but the large doses used by Dulácska ("Pest. med.-chir. Presse"; "Ctrlbl. f. kl. Med.") are noteworthy. He used the drug in four cases, one of which was complicated with pneumonia. Thirty grains of the powder were given every hour. After four doses had been taken, sleep took place, followed by profuse sweating and urination, and often by an alvine evacuation. The author attributes the effects to the action of the remedy on the intestinal nerves, but he did not observe any intestinal derangement result from its use.

Cocaine in Seasickness.—Manasseïn ("Berlin. kl. Wchnschr."; "Lancet") has used the following solution in several cases with gratifying results:

Hydrochlorate of cocaine	2¼ grains;
Alcohol	q. s.;
Distilled water	4½ ounces.

He gives a teaspoonful every two or three hours.

Lectures and Addresses.

AN ADDRESS

DELIVERED BEFORE THE NEW YORK ACADEMY OF MEDICINE, OCTOBER 1, 1885,

BY THE PRESIDENT,

ABRAHAM JACOBI, M. D.

FELLOWS OF THE NEW YORK ACADEMY OF MEDICINE: It is a source of intense gratification to me to greet you this evening in the beginning of a new season of co-operative work, after a long vacation. May the labor of the coming months be successful both for ourselves and for the medical world, *ars longa, vita brevis.* Art is so extensive indeed and life so short that we have to concentrate all our efforts to accomplish a certain amount of result.

In behalf of our common interests I crave your attention first to a few facts which I consider of great importance in regard to medical progress. They are connected with the session of the International Congress held in Copenhagen from the 10th to the 16th of August, 1884. In a general meeting held on August 14th, upon propositions made by Sir James Paget, of London, Prof. Ewald, of Berlin, Prof. Bouchard, of Paris, and Dr. Billings, of Washington, the following resolution was passed: That an international committee be formed for the collective investigation of disease, in connection with the work of the International Congress, and that a certain number of gentlemen do represent their respective countries thereon. The gentlemen designated for that purpose were Trier and C. Lange, of Copenhagen; E. Bull, of Christiania; Rauchfuss, of St. Petersburg; Ewald and Bernhardt, of Berlin; Schnitzler, of Vienna; Pribram, of Prague; Koranyi, of Buda-Pest; D'Espino, of Geneva; Bouchard, of Paris; Lépine, of Lyons; Sir William Gull and Mahomed, of London; Humphry, of Cambridge; Sir Joseph Fayrer, for British India; Gutierrez-Ponce, for South America; N. S. Davis, of Chicago; A. Jacobi, of New York; and Isambard Owen, Secretary-General, of London. The only changes which have since taken place in the list of membership have been brought about by the untimely death of Dr. Mahomed, and the addition of Axel Key, of Stockholm, and Runeberg, of Dorpat.

According to a circular distributed by the Secretary-General some time ago, "the main objects which the committee seeks to attain through the collective investigation of disease are to widen the basis of medical science, to gather and store the mass of information that at present goes to waste, to verify or correct existing opinions, to discover laws where now only irregularity is perceived, to amplify our knowledge of rare affections, and to ascertain such points as the geographical distribution of diseases and their modifications in different districts. It will be its endeavor to place clearly before the whole profession the limits and defects of existing knowledge, as well as to stimulate observation and to give it a definite direction. It will be a not unimportant incidental result of its work should it tend, as is hoped, to the better training of the members of the profession in habits of scientific and practical observation, and in systematic methods of recording the facts which they observe.

The age in which we live has seen enormous advances in the sciences on which the fabric of medicine rests—such as chemistry and other branches of physics, physiology, and pathology. Each of these has taken giant strides. It must be admitted, however, that purely medical knowledge has scarcely made proportionate progress. It can not be expected that it should do so, as it deals with the aberrations of the most complex of organisms, is of all sciences the most difficult, and demands the greatest patience and the largest accumulation of data.

Hitherto the advancement of medical science has been brought about mainly by individual effort. The value of such work in the past we in no way underrate, nor do we desire to lessen the amount of it in the future; but in medical science there is much that defies interpretation from individual experience, and many problems so far-reaching in an ever-widening field, with elements so manifold that no single man, however gifted and long-lived, can hope to bring the whole within his range. The need, therefore, in medicine of that combination and concentration of individual work which is adopted in many other branches of science and in commerce, and to which increasing facilities of intercommunication have given so much impulse and so much strength, can not be questioned. Indeed, it may be said that, resting on individual research alone, medical knowledge can be advanced but slowly and with difficulty. Future progress to any great extent must be the work, not of units acting disconnectedly, but of the collected force of many acting as one. For many to act as one, organization is needed; that organization it is the purpose of our committee to supply.

Disease is many-sided, and we wish to include in our organization those who see it from every side. All, therefore, whether hospital physicians, family and school attendants, specialists, medical officers of the army and navy and of workhouses and asylums, will be asked to contribute their quota of observations to the common fund.

These are both the motives and the propositions of the committee appointed at Copenhagen. In regard to them, and collective investigation in general, the favorable opinion of the profession has been expressed frequently. But now and then a voice is still heard disparaging its utility, and discouraging the collection of facts on a large scale for the reason that the procedure has not yet been demonstrated to be useful. Indeed it has not, for it has never been tried to a large extent. We shall hardly insist, however, that the ground-stone must not be laid because the tower is not yet on the edifice; that the seed must not be sown because the fruit can not be harvested to-day, or was not gathered yesterday.

Hesitation has also been expressed from another point of view. One of our foremost medical journals ("Boston Medical and Surgical Journal" of September 4, 1884) makes the remark that those who labor only for personal

renown will not enter enthusiastically into the work proposed by the committee. But its demands are very trifling indeed, the questions to be settled by the observations of large numbers are but few, and of such a nature as not to expropriate those who are able and anxious to arrive at and be credited with scientific results of their own, and benefit by the reputation attached to them.

If the remarks above quoted were founded on reality, whoever worked for personal reputation only would not even participate in the discussion of a scientific society, for fear that his remarks, coupled with the essay of somebody else, would miss the opportunity of being listened to as the main topic of an evening's conversation. Now, on the contrary, we are in the daily habit of seeing experience published and ingenuity displayed in just such discussions. Nor do I believe that, as another journal has it ("New York Medical Journal," September 4, 1884), "the answers coming from a great body of men of diverse views would constitute but a catalogue of raw impressions," and that, "when the facts to be observed are of a nature to call for exquisite discrimination on the part of the observers, to multiply the number of the observers is to depreciate the general quality of the work." For the more uncertain the correctness of observations is apt to be, the more numerous they ought to become. Single observations have settled a fact but very rarely. The very existence of large societies proves the instinctive demand for variety and comparative appreciation of observations. Is not every physiological fact known to us the outgrowth of a number of experiments of many men? and pathological knowledge the result of a great many autopsies by different men in many countries? What is individual experience but the accumulation of a multitude of facts of a similar nature by one man? What is science but the result of accumulated experience, collected and compared, of many men, countries, and ages? Are a hundred meteorological stations more efficient or less so than one would be? I do not belong to that class who believe a problem easy of solution merely because its solution is anxiously sought for, nor do I deny difficulties because they are obstacles to the accomplishment of cherished ends, but I know that we are in a better position to serve the co-operative work of all countries now that steam and telegraph have reduced distances, mail and travel have multiplied intercourse, and we are to-day as near St. Petersburg as our ancestors were, a hundred years ago, to Lake Erie or the James River.

Thus it appears evident that the difficulties are not excessive. As to the usefulness of collective investigation, the opinions will become all but unanimous. The efforts of the British Medical Association and the Medical Society of Berlin, and the fair success of an attempt at solving a problem connected with the ætiology of croupous pneumonia, made in the Medical Society of the County of New York during the last year, are sufficiently promising for the collective investigations of the future. In their interest it is that I propose to make a further communication and request your co-operation.

The Central Committee on Collective Investigation of the International Congress has selected the following subjects, viz.: Rickets, chorea, acute rheumatism, and cancer, planned a number of simple questions in regard to them, mainly to their ætiology, and expects as simple answers. Being the secretary of the American sub-committee, I have gathered all of them in pamphlet form, added a few introductory general remarks, supplied by the Central Committee, and present herewith a specimen for your inspection. Those of you—I hope all of you—and those of the profession at large who will learn of this request, are respectfully asked to interest themselves and their friends in behalf of the undertaking, notify me of their desire to be furnished with a copy, and comply with the suggestions of the committee contained therein. We do not look for immediate achievements. For the complex of sciences and arts called medicine has required thousands of years to arrive at its present condition; the aggregation of many wills and forces has resulted in a slow evolution only. No single discovery even, nor the first attempts at collective investigation, will effect a revolution in medicine. But what we do hope to accomplish is the gathering of facts on the strength of an improved method, the confirmation of old and the acquisition of new knowledge, and thus to contribute to the success of at least this one committee. It need not matter how much may have, nay, has, been done to mar the success of the next International Assembly, and to deprive us of the opportunity long looked forward to of greeting the giants of science, the celebrated teachers, the ingenious experimenters, and our literary or personal friends of Europe, on our own soil. For an International Congress will never convene under the roof of a house divided in itself, though the division may be the work of a few sacrilegious hands only.

But this is a sad theme, known to everybody here, deplored by everybody who feels as both a personal grief and a public calamity the humiliation which is involved in the hesitation on the part of the Congress to assemble in our country.

It is in profound sorrow that I pass by the subject; I prefer to speak of another topic, which, while it is not directly connected with any of the aims and immediate purposes of this Academy, concerns us as professional men of the State of New York and the Union. I allude to the almost unexpected success on the part of the profession of the State of New York in harmonizing a large majority of the medical men of the United States.

Let me explain. Chap. II, Art. IV, Sec. 1 of the Code of Ethics of the American Medical Association reads as follows: "A regular medical education furnishes the only presumptive evidence of professional abilities and acquirements, and ought to be the only acknowledged right of an individual to the exercise and honors of his profession. Nevertheless, as in consultations the good of the patient is the sole object in view, and this is often dependent on personal confidence, no intelligent regular practitioner, who has a license to practice from some medical board of known and acknowledged responsibility recognized by their association, and who is in good moral and professional standing in the place in which he resides, should be fastidiously excluded from fellowship, or his aid refused in consultations

when it is requested by the patient. But no one can be considered as a regular practitioner, or a fit associate in consultation, whose practice is based on an exclusive dogma, to the rejection of the accumulated experience of the profession, and of the aids actually furnished by anatomy, physiology, pathology, and organic chemistry."

This paragraph has so often been criticised by both friends and adversaries that it is unnecessary to refer again to its contradictions, its "nevertheless" and "but," and to its implied acknowledgment of modern "homœopathy." For let us not forget that the code of ethics of the American Medical Association saw the light forty years ago, and that what they call "homœopathy" nowadays differs from the Hahnemannism of those times in everything but the name. They now maintain that their practice is not based on an exclusive dogma; they profess to teach in their schools—and do teach—anatomy, physiology, pathology, and organic chemistry, and thus come up to the requirements of the above-quoted article of the code of ethics of the American Medical Association. *Indeed, if there were no better grounds for their rejection, they would to-day be entitled to membership in the association.*

What the Medical Society of the State of New York, in its sessions of 1882 and 1883, adopted in its stead ("Trans. of the Med. Soc. of the State of New York" for the year 1882, p. 75), in a code of medical ethics which covers two pages instead of the eighteen pages of the code of medical ethics of the American Medical Association ("Proceedings of the National Medical Conventions, held in New York, May, 1846, and in Philadelphia, May, 1847," Philadelphia, 1847, pp. 91–106), reads as follows:

"Members of the Medical Society of the State of New York, and of the medical societies in affiliation therewith, may meet in consultation legally qualified practitioners of medicine. Emergencies may occur in which all restrictions should, in the judgment of the practitioner, yield to the demands of humanity."

Compare with these brief sentences the explanatory declaration of the American Medical Association, passed unanimously in its session at New Orleans of April 30, 1885. There and then it was "*Resolved*, That clause first of Art. IV in the National Code of Medical Ethics is not to be interpreted as excluding from professional fellowship, on the ground of differences in doctrine or belief, those who in other respects are entitled to be members of the regular medical profession. Neither is there any other article or clause of the said code of ethics that interferes with the exercise of the most perfect liberty of individual opinion and practice.

"2. *Resolved*, That it constitutes a voluntary disconnection or withdrawal from the medical profession proper to assume a name indicating to the public a sectarian or exclusive system of practice, or to belong to an association or party antagonistic to the general medical profession.

"3. *Resolved*, That there is no provision in the National Code of Medical Ethics in any wise inconsistent with the broadest dictates of humanity, and that the article of the code which relates to consultations can not be correctly interpreted as interdicting, under any circumstances, the rendering of professional services whenever there is pressing or immediate need of them. On the contrary, to meet the emergencies caused by disease or accident, and to give a helping hand to the distressed without unnecessary delay, is a duty fully enjoined on every member of the profession, both by the letter and the spirit of the entire code.

"But no such emergencies or circumstances can make it necessary or proper to enter into formal professional consultations with those who have voluntarily disconnected themselves from the regular medical profession, in the manner indicated by the preceding resolution."

After these resolutions had been passed in New Orleans many of the professional men who always persisted in adhering to the code of the American Medical Association were of the honest opinion that they had, by accepting them, removed every discrepancy of opinion or difference of action on the part of those adhering to either the old or new code. For it is true that the explanatory declaration of Chap. II, Art. IV, Sec. 1, exhibits a great resemblance to the New York Code of 1882. For the Medical Society of the State of New York it must be a source of intense gratification to be convinced by the passing of that declaration that a few years have sufficed to so change public opinion as to oblige even the American Medical Association to recognize the justness of most of the New York proceedings. Upon this result the New York State Society can but be sincerely congratulated, and the spirit of equity and justice as displayed by the committee drafting the explanatory declaration must be commended.

The expressions of opinion in regard to the wholesome effect of the New Orleans declaration have been very numerous. I am in possession of several letters containing remarks full of satisfaction and hope. A gentleman well and deservedly known in the professions of both hemispheres, and markedly so with us for his allegiance to the code of ethics of the American Medical Association, gave enthusiastic expression to his delight over the satisfaction that declaration must give, and to the hope that the New York Academy of Medicine would give a public utterance in that direction. That would "immediately settle all difficulty about the code, and at once restore peace and harmony in the profession." I had to tell him that the Academy excluded all politics, ethical or other, from its discussions, and that the only societies which could act in the matter were the medical societies of the county and of the State of New York. There the matter then rested, for I believe I was right in excluding it from any consideration in our midst.

Still, while this Academy is no political body, old and new codes, as far as I know, being equally represented with us, we are an integral part of the body medical, and the events in the professional world affect our interests and sympathies intensely. Thus we have to regret that the wording of the resolutions of New Orleans is very likely to obscure their meaning. Emergencies are acknowledged to be binding, but, while the New York code admits that a physician may (not shall, or must) consult with a legal practitioner in a case of emergency, the explanatory declaration of the association insists that such a meeting is not a meet-

ing in the usual meaning of the term, and such a consultation "no formal professional consultation."

The differences are rather slight, it is true. If, in spite of that, the code question is still made a war-cry by some, that fact reminds us of the bloody wars and persecutions directed against former friends because of nominal differences of eccleciastical opinions in the history of the church. It is also explained by the intense enmity exhibited under all circumstances by those who have been convinced against their will. In a few instances we have to deal with the zeal displayed by converts who, after they had greeted the birth of the new code with congratulations, were induced, by certain external circumstances, to change what they call their minds within the period elapsing between the appearance of two monthly numbers. Or, what is still more—shall I say surprising, shall I say sad?—there are those who fought the new code because they longed for a fight without caring on what account. A gentleman who edited an upright and rattling journal at that memorable time, and voted "the regular ticket," and was by no means gentle toward the new-code men and principles, has convinced and assured me he never read the new code. I believe him. There are others again—their number has been large at all times—whose souls and sensibilities are moved by shibboleths, by single words, provided these words are skillfully handled by shrewd calculation.

"Just where fails the comprehension
A word steps promptly in as deputy.
With words 'tis excellent disputing;
Systems to words 'tis easy suiting;
On words 'tis excellent believing;
No word can ever lose a jot from thieving."
—*Bayard Taylor's "Faust."*

This is the element which, in skillful hands, determines for a moment the result of meetings, caucuses, assemblies. It is the emotional element, which is swayed by sentiment both false and true, by gesticulating oratory, and by implicit temporary confidence in the veracity and sound motives of its presumed leaders, which, therefore, "takes the specialists of the new-code persuasion by the tops of their heads and cuts their throats," but, after all, is cooled down by common sense, consciousness, and conscientiousness, when left to itself. Such men are in the majority. They are the waves of the ocean, always changing, now smooth and smiling, then turbulent and raving, and still always the same, steady in their general effects, now and then a disturbance and an injury, but always the eternal source of healthful development. We never cease to bless the ocean, even when it is doing its temporary worst. Let us, therefore, not despair of the future peaceful and blissful development of the country or the profession in times of turbulent commotion.

What difference is left unabolished may be left to itself until acrimony is soothed and bitterness replaced by kindness. Greater discrepancies than these have been wiped out. When the actions of men are weighed, their opinions in regard to dogmatic utterances will be disregarded. When deeds are counted, let creeds be tolerated. But let us have patience, all of us; great improvements in the universal conscience do not take place by hard fighting and refuting. Lecky is right when he says that the greatest errors can not be annihilated; it takes time for them to fade out.

In the face of the explanatory declaration passed in New Orleans which, in its main aspects, I take it, indorses the New York State Society and the spirit of the new code, the majority of those present in the meeting of the American Medical Association were guided into believing that they must protect a sacred code from infidel invaders. The main complaint was that new-code men had been given offices in the organization of the International Congress. On page 101 of the "Journal of the American Medical Association" you will find the following complaint: "Directly upon the threshold of the most important part of their work a majority of the original committee practically ignored all allegiance to the American Medical Association, and, assuming an entirely independent attitude, at once placed in the front of their ranks . . . one who was well known to have repudiated the National Code of Ethics." And, in a voluminous circular addressed to State and county medical societies, composed almost exclusively of editorials of the "Journal of the American Medical Association" and signed by the permanent secretary of the association and four other gentlemen, the following language is used: "The editorials of the 'Journal of the Association' . . . present the case" (the differences in regard to the proposed organization of the International Congress) "so clearly that there can be no doubt of the duty of the friends of the association, or of the animus of its enemies. We feel assured that your society will indorse the action of the Association, and stand firm in support of the Code of Ethics."

It is, however, fairly understood by this time that the war of the codes is over. In fact, it has always appeared to unsophisticated people that the fighting about the code was not reciprocal at all; for when the New York State Society had settled its code question to its satisfaction and that of the country societies in affiliation therewith, it appears that, in them and by them, the subject was not mentioned again except on strong provocation. You remember that it took a great deal of emphasis to relieve even this Academy of the proffered dispute. The code question is dying a great deal more easily than the bloody shirt disappeared from the politics of the country. If it is puffed up as the pivot of the organization of the International Congress, everybody is perfectly aware that this is either a pretext or a grave mistake. I believe it is both. Europeans, who were not afraid of admitting laymen and homœopathists, expected to meet, if ever they should consent to cross the Atlantic for an International Congress, the American medical profession. No International Congress must be caught in domestic quarrels, or audaciously kidnapped by a society, or a party, or the faculty of a medical school.

We are presenting a sad spectacle. In our first attempt at welcoming the medical world to our shores we have failed. The humiliation connected with this fact we have to submit to; to trace it to all its causes I can not under-

take here. The least we can do is to admit it; if the task we hoped to accomplish was too much for us, let us try to prepare for the future by attending to those duties of our own which we can perform without hindrance or disturbance.

The affairs of the Academy will require our undivided attention. In many respects we have been very successful indeed. The hall and building in which we meet is practically our own and free of debt. Thus we can look forward again to improve our quarters, enlarge our facilities, and think of securing in some near future a fire-proof building for our ever-increasing bibliographical treasures. Our income has increased with our membership. Both, however, require additions. There are many desirable men in the profession whom we ought to carry on our lists for mutual advantage.

The hopes I expressed in my inaugural address a few months ago have begun to be fulfilled. Old sections have been revived, new ones have been formed. I may here assure the gentlemen who have undertaken the task of organizing them that whatever aid the President and Council can give them in their labors will be freely offered. The sections will not only contribute to the improvement of their own members, but will enhance the interest of the general sessions by the communications coming to them from the sections, and the discussions emanating therefrom.

To enable them to begin their work, Article VI of the Constitution had to be altered. That change was brought about, in the manner prescribed by law, some months ago. It has also appeared to many fellows that more alterations are required; they have given notice of their desires in this respect, but have been unwilling to come before the Academy with any propositions to make radical changes, though in the manner prescribed by law. Now, both the constitution and by-laws may be repealed or amended by a three-fourths vote at a stated meeting, provided notice of the same has been given in writing at a previous stated meeting. But it will prove more satisfactory to guard against any mistake by trusting the work of moving proposals to change our by-laws in the hands of a committee carefully selected for that purpose. Off-hand legislation is always dangerous; it often errs, and always weakens the conservative tendencies which must underlie any political, scientific, or social structure if it is expected to last. The president expresses the hope that, if such a committee is appointed, it will be slow in considering and quick in reporting. If I am at liberty to state a wish of my own, I should say that one of the articles which require amending is that which refers to the Committee on Medical Ethics. This committee is almost powerless; it has no initiative whatsoever; in every case calling for interference or judgment, it has to wait for a charge to be preferred by a fellow; the odium of an accusation falls always on an individual member, whose unselfish interest in the welfare of the Academy or the profession is at once published, as it were, by arraying him personally against the accused. To prefer a charge is thus almost rendered an impossibility. Thus, indeed, our law is more apt to encourage derelictions of ethical duties than to prevent or punish them. Now, I am of the opinion that the interest of an accused must always be taken into account, but that that of the Academy is at least of equal importance. What the district attorney and the police are in the political and social commonwealth, the Committee on Ethics ought to be in our midst. It ought to be both authorized and directed not to wait for personal charges, but itself watch over the moral welfare of our community. If such an authority is established, the ethically weak will know that he is observed, and may be held responsible without a fellow being compelled to draw upon himself odium or revenge.

No society, either political or other, can ever do without a penal code—old or new; thus there is no harm in admitting that the Academy is in need of a committee on ethics like any other society. If the number of those who necessitate its existence or interference is but small, so much the better; but the few, when not stopped, act as bacilli of moral putrefaction. Human kind is so organized that disease-germs will operate rapidly and persistently. A committee on ethics endowed with the authority to warn and censure in time, without any procrastination, will strengthen the feeble when he feels the first symptoms of struggling against temptation, may frighten the man of harder fiber who would otherwise rely on his facilities and the difficulties on the part of the committee, and protect the interest of society and the endangered dignity of the profession.

That I speak of no imaginary evil we all know too well. What I said a few months ago of the growing tendency of a few to make the public acquainted with their merits and accomplishments through the columns of the secular press was considered timely and met with the appreciation of many members of the profession, both old and young, here and elsewhere. I mean to deserve the respect of my peers and superiors in the profession by again directing your attention to the fact that the penny-a-liners of the daily press are being utilized in the interest of, and by, weak-kneed brothers who can not stand on their own legs, who mistake cheap notoriety for reputation, and the grin of derision for the smile of approval. The more power is concentrated in commerce, the greater the prevalence which is conquered by trade, the more rampant the spirit of grasping egotism which is pathognomonic of modern industrial pursuits, the more is it the domain of the liberal professions to approximate their aims to an ideal. Let us not forget that learning by heart the action of medicines, or the working of articulations, or the proper use of an instrument, does not exhaust the possibilities of a medical man. The physician requires all that, but beyond that all the characteristics of a man of principle and intellectual and moral culture. Neither can be inculcated by the demands of old or new codes. Still, as a corporation and a profession, we are responsible for the existence of these qualities in our members. It is true, we can not supply ideals to order, nor can we make those whose eyes seek the mire raise their brow to the skies. But such as find it difficult to develop those qualities spontaneously must be taught and aided in acquiring them.

As far as I am concerned, I hope there will be no occa-

sion again to refer to the same subject during my term of service. If there is, I shall repeat my warning; for I take it for granted that when you elected me to the highest office in your possession you did so both in the belief that your candidate would have opinions and principles of his own, and on the condition that he should do his full duty.

Original Communications.

PNEUMATIC DIFFERENTIATION.*

By HERBERT F. WILLIAMS, M. D.

The article which first drew the attention of the profession to this process appeared in the "Medical Record" of January 17th of the current year. It made no pretensions to completeness, and was written with the hope that extended observation by competent men in the profession would give to the subject treated its proper therapeutic position.

This process presents some facts so self-evident that their discussion is idle. To deny all therapeutic value to such an invocation of natural laws and forces would be absurdity itself. On the other hand, the claims in its behalf already made by overzeal are equally unwarrantable. There is, therefore, a position in our therapeutics for pneumatic differentiation.

While it can not be said that experience hitherto gained has defined this position in all its relations, a few points already demonstrated will be presented, in the hope that their significance will provoke and encourage an inquiry that can not fail of wholesome results.

The five patients with phthisis reported as recovered in the original article remain in apparent health to-day, and, with the exception of two treatments given in Case No. 1 for acute bronchitis, there has been no necessity to resume. In Case No. 2 the patient has lost but one half-day from his employment as machinist since his discharge from treatment one year ago last March.

The subject of Case No. 5 has become a longshoreman, does the work of a man in his position, and commands a man's wages.

In Case No. 3 the patient remains at his employment in perfect health.

In Case No. 4 the patient is the same as reported. The slight drain from the fistulous opening in his side, however, prevents the rugged appearance of the other cases.†

On my first examination of this case, in which the principal lesion was in the left lung, I found what I regarded as primary changes taking place in the apex of the right. The present immunity from disease in the latter locality has suggested recent investigation of the other cases in which the phthisical process was confined to one lung.

I find that in no instance has the sound lung become diseased during the time of observation, and almost invariably I have been able to watch the patients until death or a subsidence of their symptoms. These observations, with their inevitable conclusions, furnish, to my mind, arguments in favor of a system of thorough antisepsis more suggestive and cogent than any hitherto offered.

The six patients with primary infiltration remain in perfect health with one exception. This patient, until two months ago, had exceeded the best weight of his life. In his occupation as solicitor he contracted a fresh cold, which ended, as before, in consolidation. Treatment was resumed, and Dr. De Watteville reports him rapidly improving.

In my investigations, formerly reported, I personally conducted the treatment. Since then the immediate administration has been in the hands of Dr. Fox in Brooklyn, and Dr. De Watteville and Dr. Tiegel in New York. Their clinical experience in more than seventy-five cases will doubtless be detailed by themselves.

They have, however, afforded me daily opportunity for consultation and continued access to their memoranda. Their courtesy enables me to make confident assurance that in their practice the relative results have been such as to confirm and emphasize the deductions originally published. Enough time has not elapsed to permit of extensive exploration in advance of the points then indicated.

I have deemed it profitable to collate many considerations which have been impressed upon me by the contemplation of this method and of the conditions in which it may be either appropriate, inadvisable, or doubtful. Many of the suggestions which I make in this connection have neither novelty nor significance except such as old and well-recognized material always assumes when brought into relation with original research in the same field.

It is suggestive of the value of the treatment that its development is in line with, and depends upon, physiological axioms. The continued use of this method will discover all degrees of adaptability and every shade of fortunate result.

If there is one thing known concerning pulmonary phthisis, it is that well-directed treatment must be early.

It is a safe, though not necessarily a correct, conclusion that, however careful may be the physical diagnosis, if we get evidence of lobular infiltration the probability is that more than one lobule is affected. If the ear detects a râle, there are several too distant for recognition.

I have long since come to base my prognosis upon an estimate of more trouble than I am able to detect. There is a great deal of truth in what I have recently seen written by an unprofessional pen: "Pure air is the life of the lung-tissue; irregularity in the supply is lung disease."

There may have been a time in our individual history when a catarrhal concretion, lodged in a remote bronchus, was the smoldering ember threatening a conflagration that would have consumed us had not one fortunate cough expelled the obstruction and removed the contingent congestion or infiltration. No one has a right to treat lightly the simplest cough when appealed to for relief or advice. Further back than this, if we, as physicians, are going to change the statistics in pulmonary consumption, we must

* Read, with a demonstration of the pneumatic cabinet, before the American Climatological Association, May 27, 1885.

† These five patients continue in good health at the present time, September 25th.

inculeate the well-known laws that are conducive to pulmonary health, and demand of the heads of our families a promise that they will compel their developing children to breathe properly.

We come, then, to the earliest opportunity when the benefits of this process may obtain. In childhood, when inflammatory action is so liable to be set up and where its consequences are so frequently overlooked on account of the elastic vitality of youth, we have a field for action in preventing the collapse of lobe and lobule and in removing all tendencies to the retardation of proper circulation, which not only produce immediate mischief, but may be, I believe, the cause of the easy development of the gravest symptoms in maturer life—as, for instance, the sudden hæmorrhage, without the appearance of a symptom that occasioned anxiety in the patient.

In the formative period of childhood and youth the proper expansion of the lungs will do much to prevent the pernicious consequences of improper frame development. The questions of treating actually instituted disease of the lung are too vast to comprehend in a single paper.

Thus far no patient able to apply for treatment has been refused, though in many instances the patients and friends have been told that temporary relief and improvement, if any, were all that could be expected. Indeed, I feel that in some cases of phthisis alleviation has been a greater achievement than recovery in others.

In any new form of treatment, and especially one as radical as this, the early applicants are those who spend most of their lives in seeking for that which they will never find, and would not appreciate if they did—viz., restoration to health. It has sometimes been difficult to exercise sound judgment and impart proper advice on account of their earnest solicitations. Such patients, if allowed, easily magnetize themselves at first, and will construe the feelings that are engendered by hope and novelty into actual improvement.

In all acute conditions such inspirations may be allowable, but the chronic cases demand the exercise of caution, though at the risk of reproach for coldness and apathy.

Through the careful labors of Dr. Austin Flint, we have been taught that there is a tendency to self-limitation in the phthisical progress.

I recognize in some cases a cessation of the severity of symptoms, and occasionally meet patients who profess to have outlived by many years the prognostication of the leaders in our profession.

So far as I know, no explanation has been offered for such conditions. I have questioned if further investigation in the life-history of the *Bacillus tuberculosis* may not bear a kindred relation to the germs of some of the eruptive fevers, where a thorough propagation renders the soil unfertile for subsequent thrift.

In a case under this treatment when, if I may so speak, the crisis has not been reached, every form of encouragement is permissible; but we meet some patients who have surprised everybody by recuperation, whose early gratitude has been succeeded, first, by two or three years of chronic process, then by growing unthankfulness, and finally by despair. They are quick to seek new devices, adopt strange methods, or grasp without discernment for anything or *everything* that promises well. When such a person applies to me he will have the benefit of my experience, which says that relief and improvement are all that can be expected.

To find a solution for this we have but to look at our post-mortem records, where fatty livers and hearts, or obliteration of the kidney cortex, with its frequent cysts and adherent capsule, plainly point to concurrent or dependent degenerative action. Where pyogenic cavities have guarded the system from frequent pyæmias, or where, from any cause, secondary assimilative or organic changes have not taken place, even though the patient may have suffered for years, I doubt not that permanent improvement or recovery may be expected.

It is to the treatment of these chronic cases that my remarks in the closing paragraphs of my first paper were mainly addressed. Good judgment suggests that rest and quiet are more applicable to some cases than ill-advised attempts at recovery, especially those that demand over-exertion in the patient. Still, such cases have been and must be met, and, with the nicety of graduation of pressure together with the influence of remedial or perhaps nutritive agents, and the certainty with which they can be introduced into the general circulation through the lungs, an improvement can be made upon what has thus far been accomplished by this process.

There is a great scope for discrimination not only in regard to the selection and administration of remedies in this manner, but also as to the force calculated to produce the best results. I have seen how unfortunate results may be ascribed to this process with which it may have nothing to do.

The irregularity of the symptoms that develop in the progress of phthisis is such that it is often difficult, if not impossible, to determine whether untoward developments are a morbid incident or the result of therapeutic error.

The subject for earliest study was that which seems at first to trouble every investigator with whom I have conversed—viz.: The effect on the pulmonary circulation with reference to production or arrest of hæmorrhage.

All seem to have an exaggerated idea of the force best calculated to produce good, and, with a fear born only of unfamiliarity, shudder at the possibilities of calamity.

It is possible that the coincidence of instant death upon the first inspiration might arise; or, through carelessness or incapacity, too much power might be exerted, which would act as a direct cause. Human fallibility is such that it may be impossible to determine the existence of fatty-degenerated bronchial walls, attenuated alveolar septa, or unprotected or aneurysmal arteries or veins.

When the totality of the symptoms points to any or all of these conditions, it is incumbent on the operator to use every possible precaution. But, when such precaution is observed, I claim for the procedure the protection accorded any measure adopted for the administration of potent agents.

Exceptional disaster could not forbid intelligent use. It would be as just to return to primeval modes of travel through fear of railroad mismanagement. It is no argument

against the therapeutic value of $\frac{1}{30}$-grain doses of arsenious acid that two or three grains may kill.

Originators in surgical procedure have outlived the obloquy of initial failure.

Chloroform is fatal as well as beneficent. But to those who are forward in their estimation of the dangers of this process I am indebted for valuable argument in its favor. It must be granted that the force is constant, for it is natural. An agent for harm may be made an agent for good when applied to suitable conditions, and its very malignity, when unrestrained, is an incentive to harness it for human welfare.

The healing art would be tame and loathsome if emasculated of every capacity for peril.

In the discussion following the very able paper read before the New York Academy of Medicine by Dr. E. D. Hudson, Jr., "On the Physical Examination of Weak Chests and Differential Diagnosis of the Several Forms of Early Phthisis," Dr. Loomis is reported as saying that "he had been able more than once to recognize the presence of acute phthisis a number of weeks before the hæmorrhage occurred which ushered it in, and by means of the peculiar harsh quality of the respiratory sounds." My confidence in the preventive power of this process, together with the influence of an appropriate astringent, in this manner applied, is such that, should my lungs be judged by him to be in this condition, I should at once resort to this treatment to forestall such calamity.

In my first paper I spoke of the way in which the capillary circulation of the lungs was reduced by this means—namely, by decreasing the resistance of the blood in its passage through the lungs by the fuller inspiratory and expiratory effort. If it was my intention to obtain the direct hæmostatic effect, I should do what is always done when we can—in other conditions of hæmorrhage—apply pressure. The distribution of the circulating vessels of the air-cells and ultimate bronchi is such that, if a continued inflation can be maintained in them, exsanguination of their walls must take place. It is possible to accomplish this by a slow, full inspiratory act under any pressure thought desirable, maintaining this as long as can be with comfort. The expiration must not be made against the external air, but into the cabinet, and, as soon as possible, a full inspiration must again be made.

Such explanation might seem inadequate, but I think will be strengthened when I say that I have never seen hæmorrhage accompanying or immediately following treatment.

In each of six cases a single seizure has occurred at intervals of from twenty-four hours to several days after the last treatment. This did not interfere with the progress of treatment.

In another case, characterized for three or four years before treatment by at least annual hæmorrhages, the patient sustained with complete immunity thirty one treatments covering the month in which he had come to expect the recurrence of his trouble, had gained two pounds and a half, and was subjectively improved, when he was overtaken by a hæmorrhage which rendered further treatment inadvisable.

We need not speak in detail of the acute conditions in which theory and practice have demonstrated the great utility of this process. As clinical evidence is gained we can more accurately anticipate the probable result of treatment in given cases. The conditions under which remedial and, perhaps, nutritive agents can be administered are such that an improvement upon previous attempts at this method can be expected.

In the pre-tubercular stage, when imperfect nutrition and assimilation are the first indications of impending disease, much may be hoped for from this form of medication. From experiments recently made, I think it a close approximation to say that from ten to fifteen per cent. of the atomized solution can be condensed upon the respiratory area. In the treatment of emphysematous conditions great benefit has been produced in three cases. This is paradoxical, for at first sight it would seem that to expand residual air would of necessity stretch its enveloping membrane and, of course, aggravate the condition.

The forces that produce emphysema are largely expiratory. In my first paper it was shown to be impossible, by any judicious resort to the force at our command, to produce over-distension. The improvement that has followed the treatment of emphysematous conditions is undoubtedly due to the subsequent increased circulation of the blood in the diseased part, and the consequent improvement in the tonicity of the alveolar walls due to improved nutrition. It may be also due to the removal of excess of catarrhal secretions in the ultimate bronchi or any anterior point. Mr. Ketchum has completed a device by which alternate rarefaction and compression of air can be made synchronously with the respiratory act, or by which either compression or rarefaction can be maintained at the will of the operator. This will enable us to obtain all the results of the compressed air-bath with which we are familiar, and to which our attention has recently been called by the lectures of Dr. C. Theodore Williams, of England, and by the methods well known throughout the Continent.

I am indebted to Dr. Teigel and Dr. De Watteville for the following report of cases occurring in their practice:

W. P. M.; occupation, barber; presented himself for examination April 18, 1885; age, twenty-seven years; colored. Best weight, 132; present weight, 120. Temperature, 101–102°. Expansion, two inches.

Condition.—Married; no children.

Family History.—On father's side, mulattoes; on mother's side, octoroons. Family history, negative.

Personal History.—A little over eighteen months ago he caught cold and could not get rid of it. He got weaker and weaker. Consulted Dr. Speir in Brooklyn; was told that his lungs were very weak, and was sent to the country. There he received great benefit, and returned, he thought, a well man. He soon fell back, however, and got very much worse. Heavy cough day and night. Complete loss of appetite; never had any pain, however. Last December coughed up quantities of heavy fœtid yellow matter. He does not expectorate much, but has a dry cough, which gives him no rest. He is losing flesh, has fever every night up to 102°, and is extremely short of breath.

Inspection.—A poorly developed thorax with insufficient expansion. Body emaciated. On both sides the thorax is flat

tened below the clavicles, amounting on the right side to a positive excavation.

Palpation.—Thorax resists pressure and is not normally elastic, especially on upper half. Vocal fremitus much increased, especially on right side.

Percussion.—Dullness and high-pitched note on right side in clavicular and supra-mammary region. Less marked on left. On right side the sound is tympanitic, and changes character and pitch when mouth is opened or shut. With open mouth it gives a typical cracked-pot sound. This tympanitic percussion note is limited to a space the size of a hen's egg. Percussion sound improves as we approach the middle third. On left side it is better than on right.

Auscultation.—On right side, in clavicular region, cavernous breathing, but not accompanied by gurgling. Vocal resonance much increased in upper third. Breathing tubular. Expiration saccadent and prolonged. Râles of every description—loud, sonorous, and sibilant—are heard in very low breathing; fine crepitant râles are observed. They diminish as we descend the thorax, and are infrequent on lower half. On left side very much the same condition exists, though not in the same degree. Dry râles are heard in front and back, but diminish gradually till they nearly cease at the base.

Course of Treatment.—Three times weekly. Began on April 18th. Commenced with $\frac{3}{10}$ inch and a spray of a solution of 1 per cent. ammon. chlorid., 5 per cent. glycerin.

April 25th.—Increased to $\frac{6}{10}$ inch. He breathes nicely, but his respirations are limited. He reports that he sleeps well at night, and that his appetite improves. He has expectorated a great deal.

May 1st.—Respiratory sounds are stronger, but râles still present in great number. The objective signs are very little changed. Subjectively, patient is in high spirits. He eats voraciously, has a normal temperature even at night, coughs during day, and expectorates heavily. He feels "splendid."

6th.—Changed to red-bark decoction (made by Mr. Beudiner, Tenth Street and Third Avenue).

12th.—Caught cold during damp days, and developed catarrh on left side. Coughs much, and does not look so well.

27th.—Marked progress. Patient has gained strength, so that he was able to assist and officiate himself in house-moving, going up and down stairs frequently. Feels none the worse for it. The left lung has recovered. On right side the râles have much diminished. On left side the improvement is marked, with exception of the region of the clavicle; the râles have nearly disappeared; here and there fine crepitant râles are heard still. The expansion is limited still, but has increased about half an inch.

The breathing in clavicular region has changed in character, the note being higher and the character more tubular than cavernous. Percussion, however, still shows the former symptoms, although the space where the cracked-pot sound is heard seems to be more limited. Subjectively, the patient's account of himself leaves nothing to desire. He coughs still, but only when he gets rid of mucus. Sleep is good, appetite good. Temperature normal. Strength improved, but by no means great. Talks of returning to work soon. He takes treatment with great regularity three times weekly, and intends continuing for some time.

M. O., aged thirty-six years, married; one child, which died of hydrocephalus and spina bifida. Patient presented himself for examination on March 28, 1885.

Family History.—On paternal side, negative; on maternal side, frequent throat troubles. One brother died four months ago of tubercular laryngitis and pulmonary phthisis.

Personal History.—Patient has for many years suffered from catarrhs, cough, and light attacks of pleuritic pains. Since New Year's the cough has much increased, often producing broken sleep, loss of appetite, and a general tired feeling; short breath on the least exertion. A dull soreness, accompanied sometimes with sharp, stitchy pains on left side, on the back, under the lower half of scapula; also on right side in the mammary region, between the fourth and sixth ribs, accompanied by wheezing at intervals. He feels feverish at night, and has to take quinine frequently. His occupation (broker) exposes him to draughts and constant changes of temperature. He is losing flesh.

Inspection.—A tall man, not very well nourished, with an extremely long and narrow thorax. Complexion pasty and pale; lower eyelids baggy; voice slightly hoarse. Hands long, clammy, and finger-nails thin, round, and bent forward extremely. Respiration jerky and quick, especially on least exertion. Respiratory movements extremely limited and chiefly abdominal. Full expansion at mammary line not quite two inches.

Palpation.—Respiratory fremitus exaggerated on right side in front, also on left side under scapula. Apex-beat of heart normal.

Percussion.—Dullness and high-pitched note, but not extreme, on the upper two thirds of right lung in front. Left side, normal resonance, except in the scapular region.

Auscultation.—*Right side front*, saccadent breathing and prolonged expiration; character vesicular. Fine crepitant râles are heard as far as the sixth rib, and very slightly in the clavicular region. In the region of nipple, fine sibilant râles at end of inspiration and during expiration. Respiratory sounds, on the whole, are feeble. *On left side front* the sounds are more normal. Behind, under scapula, loud sonorous and sibilant râles; also fine crepitant râles, especially during expiration.

Course of Treatment.—March 28th, three times weekly, $HgCl_2$ $\frac{1}{2000}$ to $\frac{1}{1000}$, with $\frac{3}{10}$ inch. Breathes with difficulty, and very jerky.

April 3d.—Complains of more pain under scapula.

8th.—Increased to $\frac{6}{10}$ inch.

11th.—Varied with inhalation of iodine.

20th.—Increased treatment to six times weekly. Tried decoction of red bark containing four and a half per cent. cinchona red (tannin).

30th.—Patient is much improved; breathes easily and fully against $\frac{8}{10}$ inch; râles nearly gone; pains gone.

May 3d.—Got his stomach out of order and got cold (neglected precautions). Sibilant râles appearing again, but with considerable expectoration.

6th.—Râles entirely gone. Pain has completely left.

10th.—Reduced to three times weekly; continue steadily with red-bark decoction.

27th.—Patient has not turned up for treatment for over a week. On last examination the objective signs were gone, as far as auscultation showed it. He is looking much better; sleeps well at night; his appetite good, at least fair; coughs a little in the morning, but not during the day. He is still a little short-breathed, but nothing like before. He should have continued for a few weeks longer, but his business, he said, called him away.

DISCUSSION.

The PRESIDENT had seen the patient to whom the author referred as having had a hæmorrhage within twenty-four hours after a treatment. The patient had had thirty-one treatments and the hæmorrhage occurred after the thirty-first. He had been under Dr. Loomis's care for four years, had, he believed spent one year in the Adirondacks, and had supposed that he had entirely recovered. At any rate, he went back to his work as a lawyer, promising to spend four months in the Adirondacks

every year. It was not necessary to mention all the physical signs which had been present; there had been well-advanced phthisis on the left side near the apex. He did not go to the Adirondacks, but to the Berkshire Hills, last summer. Dr. Loomis had not heard of him for more than a year and a half, when he was called to visit him two or three months ago while having a very profuse hæmorrhage, which had gone on for a number of days. He said that he had had the treatment according to Dr. Williams's method a great many times, but that the last time he thought there was a little carelessness in the manipulation. At least he attributed the hæmorrhage which occurred to that. The patient did not think the treatment was dangerous if it was properly administered. The hæmorrhage continued for three or four weeks. That was the only case Dr. Loomis knew of in which hæmorrhage had occurred in connection with this treatment.

Dr. Williams had one or two other patients who were doing well. One, a lady, had done very well under this special treatment. She had a cavity in the lung, and had been the world over for her health. She had remained at home the past winter, and was much better than in the autumn.

Dr. Armor, of Brooklyn, had been interested in the treatment and views of Dr. Williams, and had kept under observation some patients so treated. He thought the matter could be stated in a few propositions, some of which might have to be considered hereafter: First, the benefit of the expansion of the lungs by the apparatus without reference to the local medication. Second, the question as to whether antiseptics and other agents could be introduced more deeply into the lung substance by this means than by any other device which had been proposed. Third, the practical result, which was to be tested by clinical observation. He was aware that an instrument of this kind should be in the hands of careful observers, who were capable of diagnosticating their cases and of appreciating the results. It might be a dangerous instrument in the hands of others. He thought it should be most carefully guarded by most careful men. One case had recently come under his observation in which he had been very much interested. He carefully examined the young man before he was submitted to treatment. When he came to Dr. Williams's office he was so weak and emaciated that he had to ride in a carriage. It looked to him like a very unpromising case. He had a few weeks before an attack of pneumonia, probably on the right side. Dr. Armor found the patient, as stated, very much emaciated, feeble, rapid pulse, feeble expansion of the lung on the right side; below the scapula were marked dullness, entire absence of respiratory murmur, and above râles. It looked like a case of unresolved pneumonia. On submitting the patient to a treatment, the lips looked redder and a good deal of expansion of the lungs took place. He did not see the young man again for about a month. Dr. Williams told him that after a few days' treatment there began to be moist râles in the lower portion of the right lung and quite free expectoration. Dr. Armor found at his last examination still slight dullness below the scapula over the region referred to, but much less than formerly; there was respiratory murmur all over that portion of the lung, but a little feebler than on the other side; there were no moist râles. The symptoms had entirely abated; there was absence of fever, the general appearance was good, the appetite good; he had gained about a pound a week, and had walked a distance of two miles to his office. There was certainly a very remarkable improvement in the condition of the lung, whether it was due to constitutional treatment or to the instrument. He had had thirty-one treatments. In a letter to him, Dr. Bowditch, of Boston, had said it was his impression that this treatment would mark a new era in the management of pulmonary affections.

HYDRONAPHTHOL;
A NEW ANTISEPTIC.

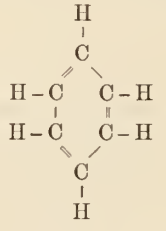
By GEORGE R. FOWLER, M. D.,
SURGEON TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

Hydronaphthol, the subject of the present article, has only recently been discovered, and this is believed to be its first introduction into surgical practice. It was in the belief that it would be found of value in the treatment of wounds that I began the investigation of its antiseptic properties in the early part of the present month, when my attention was called to the compound by Mr. W. J. Rigney, of New York, to whom I am indebted for the facts regarding its composition herewith presented.

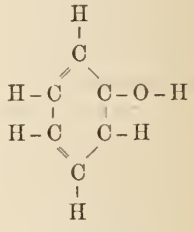
Hydronaphthol belongs to the phenol series, and bears the same relation to naphthyl, the hypothetical compound radical of naphthalin, that carbolic acid does to the compound radical phenyl. Thus, carbolic acid was formerly regarded as the hydrated oxide of phenyl. Hydronaphthol, considered in the same way, would be a hydrated oxide of naphthyl. The following formula will show the analogy:

Carbolic acid, $C_{12}H_5O$, HO;
Phenyl, $C_{12}H_5$
Hydronaphthol, $C_{20}H_7O$, HO;
Naphthyl, $C_{20}H_7$.

At the present time, however, these hypothetical compounds, phenyl and naphthyl, are considered as being obsolete, and not capable of existing. In fact, carbolic acid is regarded as an oxide of benzol, or as a benzol in which one of the hydrogens is substituted by one hydroxyl (O H). According to the graphic formula of Prof. Kekulé, this substitution occurs as follows:



Benzol.



Carbolic Acid.

In the aromatic hydrocarbons are found many isomerical substances. This peculiar identity in chemical composition, associated with varying physical properties, can only be accounted for by a difference existing in the arrangement of the atoms in the molecule. The graphic formula as above illustrated is well adapted for explaining the relations and properties of these aromatic compounds, of which benzol is the prototype. Thus, in all the monosubstitutions of benzol there is but one compound possible; no matter in what position the substitution takes place, the product must be the same. As seen in the preceding formula (carbolic acid), the hydroxyl (O H) substitution takes place in the first position, but the product would be the same if it were to take place in any of the other five positions. While this is true of the monosubstitutions of benzol, the disubstitutions are capable of forming three different compounds, identical in chemical composition but very different in their physical properties.

A knowledge of the relation, constitution, and properties of these substances is indispensable to an intelligent appreciation of their usefulness and application; and, as all the so-called phenols possess, in a greater or less degree, antiseptic properties upon which their value in surgical science as well as preventive medicine depends, I may be pardoned for thus alluding to some recently developed facts in their chemistry, in this connection.

Naphthols are the hydroxyl substitutions of naphthalin, and are two in number, commonly known as Alpha- and Beta-naphthol. These are made by heating naphthalin with sulphuric acid. Alpha-naphthol is formed when 60° to 90° C. is reached, and Beta-naphthol at from 180° to 190° C. The Alpha- or Beta-naphthalin-monosulphonic acid thus formed is treated with sodium hydrate, and is decomposed into sodium naphtholate, sodium hydrate, and sodium sulphite. Naphthol is obtained from the sodium naphtholate by decomposing it with hydrochloric or sulphuric acid; it is then purified by distillation.

Hydronaphthol is a derivative of the hydroxyl substitution of naphthalin, which latter of itself possesses antiseptic properties of sufficient value to have already excited notice and a desire to learn more of its compounds. The term "hydronaphthol," although perhaps not, strictly speaking, correct, yet conveys sufficiently well its character and relations to naphthalin, and at the same time is a convenient term for every-day use. It has been but recently discovered that it possesses antiseptic properties, and the claim is made that it is from ten to fifteen times more efficient than carbolic acid. It is the most promising antiseptic of the phenol series, and, besides, possesses so many other advantages over substances now used for this purpose that it bids fair to supersede many of these. In surgical practice it will take the place, probably, of carbolic acid. Of the many new members of the phenol series which have been discovered since Calvert called attention to carbolic acid about thirty years ago, and which have been utilized in the industrial arts, some are better antiseptics than the latter. With but one or two exceptions, however, none have obtained any prominence as germicidal agents. Carbolic acid, though a fairly reliable antiseptic in strong solutions, when so used, involves some risk to life, from its corrosive action upon animal tissues and well-known poisonous properties. In weak solutions it is exceedingly unreliable, and its disagreeable odor often hides that of putrefaction, instead of preventing the occurrence of the latter. On the other hand, hydronaphthol is non-irritant, non-poisonous, and non-corrosive; and, although only soluble in water to the extent of one part in one thousand, in this proportion is antiseptic. It has no odor to disguise that of putrefaction, nor is it decomposed or rendered inert by the products of putrefactive decomposition—such as sulphureted hydrogen, ammonia, etc. It is far more stable than carbolic acid, not being volatile at ordinary temperature. Its vapor, when volatilized for purposes of fumigation, has no obnoxious effect upon the organs of respiration. It will not injure, either in substance, solution, or vapor, colors or textile fabrics. Its sparing solubility in water is rather an advantage than otherwise, as mistakes in making solutions can not occur. A saturated solution is about of the strength of one to one thousand, and in this proportion it will perfectly preserve for an indefinite time animal tissues and fluids, and yet upon living tissues this solution produces no perceptible effect other than the formation of a very slight albuminate film—this latter to be considered rather an advantage than otherwise, inasmuch as it constitutes an additional security against infectious germs floating in the air. If for no other reason than that it is non-corrosive, and hence will not injure the polished surface and keen edge of cutting instruments, it is to be preferred to mercuric bichloride, and to the latter it is second only in antiseptic qualities. It has a slight aromatic taste and odor, and crystallizes in scale-like clinorhomboid laminæ of a silvery white or grayish hue. Although but sparingly soluble in water, it dissolves freely in alcohol, ether, chloroform, glycerin, benzole, and the fixed oils. It is not volatile at ordinary temperature, but begins to sublime at about 90° C. With the alkalies and the alkaline earths it forms compounds which are unstable, are readily decomposed by carbonic acid, and of doubtful antiseptic value. It is easily powdered, and in this condition, triturated with carbonate of magnesia, silicates, such as fuller's earth, China clay, etc., in the proportion of two parts of the hydronaphthol to one hundred of either of the above named, can be dusted along the line of incision and over the mouths of drainage-tubes, in the latter application having an advantage over iodoform, now so commonly used for that purpose, in that it does not dry up the serum escaping from the wound cavity, and thus block up the exit extremity of the tube. Absorbent gauze, cotton, jute, wood-flour, sawdust, peat, moss, and paper-wool may be impregnated with it by immersing them in its alcoholic or benzole solution and then drying; the hydronaphthol crystals cling to these without the aid of stearin, paraffin, or resin, as in the case of carbolic acid. As it is not decomposed by the presence of organic matter, it possesses this advantage over corrosive sublimate in the preparation of surgical dressings. Its ten-per-cent. alcoholic solution perfectly sterilizes silk, and sufficiently hardens and preserves, as well as sterilizes, catgut.

ISOLATION OF THE TEMPERATURE SENSE IN THE ORO-PHARYNGEAL CAVITIES AND NASAL PASSAGES BY MEANS OF COCAINE.*

By JOHN N. MACKENZIE, M. D.,
BALTIMORE.

My attention was first called to the isolation of the temperature sense by means of cocaine through an observation of Dr. William Warfield, of this city, who noticed during an operation on the eye (under the anæsthetic influence of this drug), performed by Dr. Russell Murdoch, that, while the sensibility of the conjunctiva and cornea was abolished, the contact of the instruments was felt as a distinctly cold

* Read by title before the American Laryngological Association, June 25, 1885. See also letter in (Philadelphia) "Medical News," May 30, 1885, on "Isolation of Temperature Sense."

sensation. Subsequently Mr. H. H. Donaldson, of the Johns Hopkins University, acting upon this hint, examined the eyes of two patients with reference to this singular fact, and discovered that, although the eye was rendered completely insensitive, the sensations of heat and cold were readily distinguished.

Struck with the original observation of Dr. Warfield, I experimented with regard to the isolation of the temperature sense in the nasal and oro-pharyngeal cavities. Six persons (hospital patients) were taken for the experiments. Having thoroughly anæsthetized the mucous surfaces of the soft palate, uvula, and nasal passages with a four-per-cent. solution of cocaine, a probe, which had been previously immersed in a mixture of ice and salt, was made to impinge upon the parts rendered insensible to contact and pain. A distinct sensation of cold was complained of in each instance. The opposite extremity of the same probe was then heated over the burner of a lamp used for laryngoscopic purposes, and in its heated condition carried over the anæsthetized area. While absolutely no pain was felt by any of those experimented upon, there was a marked unanimity of the answers, given voluntarily, in regard to the sensation of heat. In three of the cases an eschar followed the application of the heated probe, and in one an acute pharyngitis developed; yet at the time of application no pain was felt, though the temperature sense remained intact. These observations are of interest, in view of the fact that, while recent physiological research has rendered it probable that the sensations of heat and cold are distinct from those of mere contact and pain, it has heretofore been impossible to demonstrate the fact by the complete isolation of the temperature sense. It is accordingly obvious that its separation from the other senses may lead the way to more interesting physiological discovery.

A CASE OF
SUBMUCOUS LARYNGEAL HÆMORRHAGE COMPLICATED WITH CYST.*

By FRANK L. IVES, M. D.

Having been unable, after careful search, to find among the few recorded cases of cyst of the vocal bands anything resembling the following, it has seemed to me worth while to present it to your notice:

A robust man, about forty years of age, whom I had previously treated for a slight catarrhal affection of the larynx, called upon me on April 25th and gave the following history: The night before he had exerted his voice to an unusual degree at a public meeting. He felt no inconvenience after returning to his home, but, on waking the next morning, at first had great difficulty in making himself heard. Afterward his voice grew a trifle clearer. He had no pain or soreness in his throat, nor had he any difficulty in breathing. The only sensation was one of irritation, which caused him to "hack" almost continually. When he came to me he could only speak in a hoarse whisper. Examining his larynx, I found it to be normal in shape and color, except the left vocal cord, which was swollen uniformly throughout its entire length to about twice its natural size, and was a bright red in color, the coloring being perfectly even. My patient being forced to leave that evening, I directed him to use a soothing inhalation, and use his voice as little as possible. On May 2d he called upon me and stated that his voice had improved somewhat, but the irritation still remained. Examination showed the left cord to have returned to its normal size, and to be only slightly congested, but upon the edge and near the middle there was a smooth, glistening tumor, of about the size of a pea and light brown in color. It was not pedunculated, and its origin seemed to be merged in the substance of the cord. On touching it with a probe it was easily indented, but quickly returned to its original shape. Being convinced, from the appearance of the growth, that it was a cyst with sero-sanguineous contents, I proposed to my patient to make an incision into the growth, but also told him that the growth would disappear without any operation—how soon, I could not say. He preferred to wait. Four days after he called upon me and stated that the previous evening, while at dinner, he had a violent paroxysm of coughing, caused by some food going the "wrong way." When he recovered, he found to his delight that his voice was perfectly clear. Examination showed the growth to have disappeared.

* Read before the American Laryngological Association, June 25 1885.

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

A System of Obstetric Medicine and Surgery, Theoretical and Clinical, for the Student and Practitioner. By Robert Barnes, M. D., Obstetric Physician to St. George's Hospital, Consulting Physician to the Chelsea Hospital for Women, etc., and Fancourt Barnes, M. D., Physician to the Royal Maternity, Charity, and to the British Lying-in Hospital, etc. Illustrated with Two Hundred and Thirty-one Wood-cuts. Philadelphia: Lea Brothers & Co., 1885. Pp. xxiii–884.

A Practical Treatise on the Diseases of Children. By Alfred Vogel, M. D., Professor of Clinical Medicine in the University of Dorpat, Russia. Translated by H. Raphael, M. D., formerly House Surgeon to Bellevue Hospital, Physician to the Eastern Dispensary for the Diseases of Children, etc. Third American, from the Eighth German, Edition. Illustrated by Six Lithographic Plates. New York: D. Appleton & Company, 1885. Pp. xii–640. [Price, cloth, $4.50; sheep, $5.50.]

Plumbing Problems; or, Questions, Answers, and Descriptions relating to House Drainage and Plumbing, from the "Sanitary Engineer." With One Hundred and Forty-six Illustrations. New York: "The Sanitary Engineer," 1885. Pp. xiv–244.

Practical Therapeutics: a Compendium of Selected Formulæ and Practical Hints on Treatment, Systematically Arranged, Interleaved, and copiously Indexed. By Edward J. Bermingham, A. M., M. D., Fellow and ex-Vice-President of the American Academy of Medicine, etc. New York: J. R. Bermingham, 1885. Pp. 6–420.

Transactions in the Texas State Medical Association, Seventeenth Annual Session, held at Houston, Texas, April 21, 22, and 23, 1885. Austin, Texas: Printed for the Texas State Medical Association. Pp. 1–430.

Consanguineous Marriages: their Effect upon Offspring. By Charles F. Withington, M. D., of Roxbury. Read at the Annual Meeting of the Massachusetts Medical Society, June 9, 1885.

United States Consular Reports. Supplementary Reports on Cholera in Europe in 1884. Washington: Government Printing-Office, 1885. Pp. 1–12.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. APPLETON & Co. Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, OCTOBER 3, 1885.

THE SURGEON-GENERALSHIP OF THE MARINE-HOSPITAL SERVICE.

WE lately took occasion to deprecate the efforts that, it was alleged, were being made to induce the Administration to dismiss Dr. Hamilton from the office of Surgeon-General of the Marine-Hospital Service, for it was evident that there were no other grounds for those efforts than the yearnings of a horde of office-seekers—so evident that we expressed our disbelief in the probability of any such action being taken by the President or the Secretary of the Treasury. Dr. Hamilton has not yet been superseded, and we still hold to the conviction that the Administration would not finally have dismissed him, no matter what pressure might have been brought to bear on it. Since the article we have referred to was written, however, Dr. Hamilton has tendered his resignation of the office, preferring, no doubt, to take the initiative, as the matter had excited public attention. This course on his part may be taken to be indicative of a sensitiveness that is the natural accompaniment of those other qualities that have made him so efficient and satisfactory an officer; but it does not in the slightest degree relieve the Administration of its plain obligation not to allow of so flagrant a violation of the spirit of civil-service reform as the supersession of this officer, even by the acceptance of his resignation. Dr. Hamilton is young, active, and enthusiastic in his work—a work that to a great extent he himself has organized—and it is not to be supposed that he is anxious to shift the burden of his responsibilities to untried shoulders, and relapse into the quiet of a subordinate position. His resignation is undoubtedly due to the machinations we have spoken of, and our belief is that the President will readily foresee the interpretation that the friends of civil-service reform would put upon his acceptance of a resignation called forth by the circumstances of this case. We are glad to be able to add that there are indications that the resignation will not be accepted.

We have lately received a letter from a medical officer of the Marine-Hospital Service, in which he thanks us for the editorial article which we published on the subject in our issue of September 19th, and goes on to say that he, as a Democrat, can not but regret that Dr. Hamilton should feel compelled to resign, during a democratic Administration, solely for political reasons, when, by his continuance of the policy of the late Surgeon-General Woodworth, the service was taken out of politics, and Democrats were enabled to enter it on their literary and professional merits solely. He expresses his conviction that there is not an officer in the corps so competent to administer its affairs as Dr. Hamilton, and that a political appointment would, by a single stroke, destroy the bright prospects of the corps as a harmonious body of workers. Finally, he hopes that we may find time and opportunity to urge Dr. Hamilton to withdraw his resignation. We presume that Dr. Hamilton could hardly be induced to take this course, except by the request of the President or the Secretary of the Treasury, and, indeed, apart from his natural disinclination to do so, it seems to us better that the responsibility should rest, as it now does, solely upon the Administration. The President has given abundant evidence of his desire to further the efficiency of the public services, and we doubt not that, now that Dr. Hamilton's resignation will soon bring this matter pointedly to his notice, he will himself furnish the readiest solution of the difficulty by declining to countenance the sacrifice of the best interests of the Marine-Hospital Service to those of the spoils system.

MINOR PARAGRAPHS.

THE ANTI-VACCINATION FEELING IN MONTREAL.

A DISPOSITION to make the best use of the gifts sent by the gods can not be said to have been strikingly exemplified of late by a considerable portion of the people of Montreal. Indeed, they seem rather to have taken pleasure in ranging themselves with those conservatives of whom it was said in "The New Gospel of Peace" that when they had fallen into hot water they would suffer no man to pluck them out, lest they should be scalded. It has been almost inconceivable to the great majority of the people of this continent that so enlightened a city as the Canadian metropolis should for years have been the scene of the only considerable opposition to vaccination that has shown itself in America since the practice was established. There is, to be sure, a wide-spread feeling that it would be unwise to make vaccination generally compulsory, as is done in many European countries, but it would be difficult to find a community in the United States that would offer any serious opposition to temporary compulsion during the prevalence of a small-pox epidemic. Such an opposition has been manifested in Montreal for many years past, and in consequence the city has suffered severely from small-pox at short intervals.

During the past week actual rioting has taken place, and both the sanitary and the police authorities seem to have been sadly unprepared for it. Physicians and members of the Board of Health have suffered violence, and even a poor apothecary, whose sole offense was that of including vaccine virus among the commodities that he kept for sale, has had a like experience. The anti-vaccination bigotry is said to be mostly confined to the French Roman Catholics. If this is the case, it would seem to be nursed more as a pretext for a war of races and of creeds than from any traditional or inherited prejudices, for we have never supposed that the Church of Rome was opposed to vaccination, and certainly the French as a nation have been unsurpassed in its maintenance. It is curious to observe that the French-Canadian anti-vaccinationists seem bent upon upholding two somewhat remarkable allegations—first, that during the present epidemic the French have not been stricken with the disease in greater proportion than the English, and second, that small-pox is rather a good thing to have. Meantime, the trade interests of Montreal are suffering severely.

THE AMERICAN GYNÆCOLOGICAL SOCIETY.

IN this issue we conclude our report of the tenth annual meeting of the society, which was held in Washington last week. The proceedings are certainly to be ranked with those of the

most successful meetings that the society has ever held, and we shall be much surprised if the sale of the tenth volume of the "Transactions" does not show a continuation of the increase of the demand for the series that has been apparent during the past two or three years. Much of the success of any given meeting of such a society depends upon those of the members who reside in the city where it is held, and upon the extent to which they succeed in enlisting the co-operation of the local profession. Taking this view of the matter, we can not too highly praise the Washington members, who, together with a great number of the leading physicians of that city, exerted themselves most effectively to make the meeting and the occasion satisfactory and enjoyable. We understand that but four members of the Washington Obstetrical and Gynæcological Society were absent from the dinner which that organization gave to the fellows of the American Gynæcological Society, and that those four were either sick or absent from Washington. In view of the membership to which this young society has already attained, the fact is not a little remarkable, and it affords a striking proof of the zeal with which the obstetricians and gynæcologists of Washington entered into the spirit of the occasion. We trust that, as Dr. Busey suggested in his address of welcome, the American Gynæcological Society will not allow another decade to pass before it again chooses Washington as its place of meeting.

A MEDICAL MISSION.

Usually our Government is averse to spending money for scientific purposes, and it must be confessed that the underlying theory of our Constitution rather calls for that sort of policy. It seems sometimes, however, that there is too little disposition to yield the theoretical point before the pressure of an urgent need of scientific information of a nature to lead directly to results of the greatest practical importance to the whole people. It is pleasant to be able to record exceptions to this traditional inertia, especially of the sort mentioned in our news columns—that, namely, of the appointment of Dr. Shakespeare, of Philadelphia, as a commissioner to visit the scenes of cholera prevalence in Europe, for the purpose of studying the disease and the methods resorted to for controlling its ravages. No more important subject could engage the attention of the Government at the present time, and it would be difficult to find a man better qualified than Dr. Shakespeare to carry on the inquiry.

THE BROOKLYN PATHOLOGICAL SOCIETY.

In another column we publish the programme for the meetings of this society, from October 8, 1885, to June 10, 1886. It will be seen that the list of authors is made up of the names of gentlemen who are widely and favorably known for their previous contributions, and that the subjects upon which they are to read papers relate to a very wide range of the subdivisions of medical science. These formal papers constitute, of course, only one element of the work with which the society will be occupied during the season, but in themselves they will form an achievement that any such society might well be proud of. The fact that the whole list could be made out before the society season had begun betokens the society's continued activity, but our readers, who have had its proceedings laid before them for the past year or more, need no such proof of its efficiency.

NEWS ITEMS, ETC.

The Montreal Small-pox Epidemic shows rather an increase than any diminution. There were fifty-six deaths in the city and its suburbs on Sunday, seventy-nine on Monday, and eighty-four before four o'clock on Tuesday. It is gratifying to learn that some at least of the Roman Catholic clergy have advised the members of their congregations to submit to vaccination, and that the Sisters of Providence are doing still greater service by reporting cases of the disease to the Board of Health. The sanitary officials of the city are reported to have asked the New York Health Department to send one or more of their *attachés* to Montreal, to assist in the organization of a plan of managing the epidemic, but it is stated that our Commissioners have concluded that it would be unwise to grant the request. The latest estimate gives the number of cases now in progress as between three thousand and thirty-five hundred.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending September 29, 1885:

DISEASES.	Week ending Sept. 22.		Week ending Sept. 29.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	59	13	39	16
Scarlet fever	15	1	15	2
Cerebro-spinal meningitis	4	5	2	2
Measles	4	2	4	0
Diphtheria	46	30	39	19
Small-pox	2	2	3	3

A Vaccination Riot broke out in Montreal on Monday, the occasion of which was the passage of an ordinance by the Provincial Board of Health making vaccination compulsory. The house of a health officer, Dr. Laberge, was stoned, and the Board of Health's central office was then attacked, and several women among the applicants for vaccination are said to have been struck with the missiles. After threatening a newspaper-office and making sundry other demonstrations, the mob visited the houses of Dr. Lachappelle, of the Board of Health; Dr. Laporte, a public vaccinator; M. Grenier, a public official; and the shop of an apothecary who sold vaccine virus. At each of these places violence was displayed, and Dr. Laporte's house was set on fire. A renewal of the rioting on the following day seems only to have been prevented by a prompt and overwhelming display of military force.

The Cholera in Europe.—Dr. Edward O. Shakespeare, of Philadelphia, has been appointed United States Commissioner to investigate the cholera in Europe, with special reference to the recent outbreak in Spain. He sails next week with *carte blanche* from the Government, and will be absent about three months.

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, September 23d: *Montreal, Canada.*—For the week ending September 23d: 235 deaths from small-pox. No report of the number of cases. From September 21st to 23d, inclusive, there were 31 deaths from small-pox in four municipalities adjoining Montreal. *Three Rivers, Canada.*—For the week ending September 19th: 5 cases of small-pox; the disease is increasing. *Toronto, Canada.*—September 23d: Free from small-pox. *Cardenas*, September 12th, *Matanzas, Cuba*, September 23d, and *Nassau, N. P.*, September 19th: Free from epidemic diseases. *Guaymas, Mexico.*—Consul reports, September 23, yellow fever in *Sonora*. From September 1st to 23d there were 138 cases and 36 deaths. The disease has also reappeared in *Hermosillo*, there having been, from September 7th to 23d, 12 deaths. At *Ortiz* station several deaths from

yellow fever have occurred among the soldiers. *Vera Cruz, Mexico.*—Consul reports, September 8th, yellow fever still prevalent, the mortality being about 50 per cent. *La Guayra, Venezuela.*—September 5th: Free from epidemic diseases. *Cartagena, Colombia.*—Consul reports, August 28th, that 28 cases of yellow fever have occurred at intervals during the past three or four months. Masters of vessels for ports in the United States generally decline to take bills of health. *Callao, Peru.*—For the week ending August 22d: 5 cases of small-pox. *Paris, France.*—For the week ending September 12th: 12 deaths from small-pox. *Bordeaux, France.*—For the week ending September 12th: 7 deaths from small-pox. *Marseilles, France.*—September 7th: Cholera reported at *Cette*. *Cadiz, Spain.*—September 5th; Cholera officially declared September 3d. The average weekly mortality is about 40 per cent. During the week ending September 3d the mortality was 147. *Gibraltar, Spain.*—Five cases and 5 deaths from cholera during the twenty-four hours ending on September 5th. No new cases were reported. *Santander, Spain.*—September 10th: Cholera increasing. *Genoa, Italy.*—September 10th: 2 cases of small-pox. *Rome, Italy.*—By telegram September 2d: 4 deaths from cholera, nine miles from *Genoa*, and 5 deaths from the same disease fifty miles north of *Naples*. *Leghorn, Italy.*—By telegram, September 25th: 3 cases and 1 death from cholera at *Pontremoli*, Province of Carrara. *Palermo, Italy.*—September 24th: 1,279 cases and 780 deaths from cholera to date. *Venice, Italy.*—By telegram September 22d: 5 cases of cholera on the 21st in towns on the banks of the Po. *Trieste, Austria.*—September 8th: 26 cases of small-pox; the disease increasing. *Zurich, Switzerland.*—September 5th: 4 deaths from small-pox. *St. Petersburg, Russia.*—August 29th: 8 deaths from small-pox. *Warsaw, Russia.*—September 5th: 3 deaths from small-pox. *Calcutta, India.*—August 15th: 16 deaths from cholera, and 3 from small-pox. *Columbo, Ceylon.*—August 3d: Cholera reported in Nativetown. *Shanghai, China.*—August 21st: Cholera continues among the Chinese in the settlement and in the city; 1 death among the shipping population. From August 17th to 27th, inclusive, there were in Spain 55,785 cases and 17,856 deaths from cholera. The total number of cases and deaths from March 4th to August 27th is 214,958 cases and 81,496 deaths.

Japanese Regulations against the Spread of Cholera from Nagasaki.—Imperial Decree No. 31.—It is hereby decreed that vessels arriving from localities infected with cholera shall be inspected according to the following regulations:

Regulations for the Inspection of Vessels arriving from Localities infected with Cholera.

1. All vessels arriving from localities infected with cholera shall be subject to medical inspection, and no vessel so arriving shall proceed to her destination or communicate with the shore or other vessels, or land her crew, passengers, or cargo, until a written permission so to do, signed by one of the inspecting officers, shall have been so granted as hereinafter provided.

2. When there are no cholera patients, or bodies of persons who may have died of the said disease, on board such vessels, the inspecting officers shall forthwith grant permission to such vessels to proceed to their destination and communicate with the shore or other vessels, and to land their crew, passengers, and cargo.

3. Vessels so arriving and having on board cholera patients, or the bodies of persons who may have died of the said disease, shall be required to anchor at a place designated by the inspecting officers at a safe distance from the land and other vessels.

The patients shall be sent to the Quarantine hospital or to their residences or other places which the inspecting officers may deem suitable. The dead bodies (if any) of persons who may have died of the said disease shall (at the option of persons interested, if any) be either burned at a place prepared by the local authorities for that purpose, or buried, after undergoing thorough disinfection, at such place as the local authorities may designate.

After final disposition of such patients and dead bodies (if any) shall have been made, the inspecting officers shall thoroughly disinfect the crew and passengers, and shall thereupon grant permission for them to land. The inspecting officer shall thoroughly disinfect said vessels and such portion of their cargoes as may be considered to be of an infectious character, and thereupon grant permission for them to proceed to their destination or communicate with the shore or other vessels and to land cargo.

4. Any person or persons who shall contravene or infringe the provisions of the foregoing regulations, or shall in any manner interfere with the execution of said provisions, shall be punished according to the criminal code.

5. The localities where these regulations shall be put in force, and the length of time for which they shall be continued in force, will be determined from time to time by the Minister of the Interior.

Dated 23d of the 6th month, 15th year Meiji.

By command of H. I. M. the Emperor.

(Signed) { Sanjo Sanetomi, *Prime Minister.*
{ Yamada Akiyoshi, *Minister of the Interior.*

Personal Items.—Among the passengers who sailed for Europe by the steamship Etruria, on Saturday last, was Dr. George M. Sternberg, of the army. Among those who arrived by the Servia, on Sunday, were Dr. W. S. Ely, of Rochester, and Dr. T. H. Burchard, of New York. Dr. William S. Halsted, of New York, sailed for Europe in the Werra on Wednesday.

The Surgeon-Generalship of the Marine-Hospital Service.—As we go to press, we learn that the President has decided not to accept Dr. Hamilton's resignation.

The German Faculties.—The "British Medical Journal" states that Dr. Penzoldt has been appointed to succeed Prof. Leube at Erlangen, and that Dr. Ludwig Stieda, of Dorpat, is to succeed Prof. Meckel in the chair of anatomy at Königsberg.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 20 to September 26, 1885:*

Promotions.

McParlin, T. A., Lieutenant-Colonel and Assistant Medical Purveyor. To be Surgeon, with rank of colonel, to date from September 16, 1885.

Irwin, B. J. D., Major and Surgeon. To be Assistant Medical Purveyor, with rank of lieutenant-colonel, to date from September 16, 1885.

Pope, B. F., Captain and Assistant Surgeon. To be Surgeon, with rank of major, to date from September 16, 1885.

Appointment.

Morris, Edward R. To be Assistant Surgeon, with rank of first lieutenant, to date from September 17, 1885.

Ainsworth, F. C., Captain and Assistant Surgeon. From Department of Texas to New York city, for duty as recorder of the Army Medical Examining Board. S. O. 214, A. G. O., September 18, 1885.

Adair, G. W., Captain and Assistant Surgeon. Granted leave of absence for one month, with permission to apply for one month's extension. S. O. 104, Department of Dakota, September 18, 1885.

Shannon, William C., Captain and Assistant Surgeon. Granted leave of absence for four months, to take effect about October 1st. S. O. 215, A. G. O., September 19, 1885.

Bushnell, George E., First Lieutenant and Assistant Surgeon. Ordered from Department of Dakota to Department of the East. S. O. 219, A. G. O., September 24, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy during the two weeks ending September 26, 1885.*

Murray, J. M., Passed Assistant Surgeon. Resignation accepted, to take effect January 1, 1886.

Ross, J. W., Surgeon. Assigned to special duty at New York.

Dungan, J. S., Medical Director. Waiting orders.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the five weeks ended September 26, 1885.*

Vansant, John, Surgeon. To proceed to New Orleans, La. September 16, 1885.

Hutton, W. H. H., Surgeon. When relieved, to proceed to Mobile, Ala. September 16, 1885.

Long, W. H., Surgeon. Granted leave of absence for ten days, September 1, 1885. When relieved, to proceed to Detroit, Mich. September 19, 1885.

Fessenden, C. S. D., Surgeon. To proceed to Norfolk, Va. September 16, 1885.

Sawtelle, H. W., Surgeon. When relieved, to proceed to San Francisco, Cal. September 18, 1885.

Godfrey, John, Surgeon. When relieved, to proceed to Louisville, Ky. September 16, 1885.

Goldsborough, C. B., Passed Assistant Surgeon. When relieved, to proceed to St. Louis, Mo.

Austin, H. W., Surgeon. To proceed to Burlington, Vt., on special duty. September 23, 1885.

Society Meetings for the Coming Week:

Monday, *October 5th:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Medical Society of Monmouth County, N. J. (Freehold); Chicago Medical Society.

Tuesday, *October 6th:* New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Broome (annual), Columbia (annual—Hudson), Orange (semi-annual—Goshen), and Schoharie (semi-annual), N. Y.; Medical Association of Northern New York (annual—Malone); Medical Societies of Hudson (Jersey City) and Union (quarterly) Counties, N. J.; Androscoggin County, Me., Medical Association (Lewiston); Chittenden County, Vt., Medical Society.

Wednesday, *October 7th:* Medical Society of the County of Richmond (Stapleton), N. Y.; Penobscot County, Me., Medical Society (Bangor); Philadelphia County Medical Society.

Thursday, *October 8th:* Harlem Medical Association of the City of New York; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; New York Laryngological Society; South Boston, Mass., Medical Club (private); Pathological Society of Philadelphia.

Friday, *October 9th:* Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y. (anniversary).

Saturday, *October 10th:* Obstetrical Society of Boston (private); Worcester, Mass., North District Medical Society.

Proceedings of Societies.

MEDICAL SOCIETY OF VIRGINIA.

Sixteenth Annual Meeting, held at Alleghany Springs, Tuesday, Wednesday, and Thursday, September 15, 16, and 17, 1885.

Dr. Bedford Brown in the Chair.

Tuesday's Proceedings.

Medical Societies: their Relations to the Public, was the title of the annual address to the public and to the profession, delivered by Dr. H. M. Clarkson, of Haymarket, Va.

Medicinal Properties of Alleghany Waters.—Dr. Isaac White, resident physician at Alleghany Springs, Va., presented a paper on this subject, and said that the geological formations in this section consisted mostly of magnesian limestone and argillaceous slates. Ores of iron, silver, lead, and zinc were near by. The water of the Springs had a temperature of 56° F., and the specific gravity was 1·00283; it had a saline taste and a faintly acid reaction. In giving the analysis, he incidentally remarked that the effects of baryta and strontia were somewhat similar to those of arsenic. He had not become such an enthusiast in regard to the Alleghany water as to claim for it specific properties for every disease, but the range of its efficacy was distinct and extensive. He recommended the water especially in dyspeptic cases, using the term "dyspeptic" in its generic sense. He believed the magnesian salts in this water were their great power. Frequently, when first taken, the water produced a strange feeling in the head—a giddiness which was often closely followed by decided headache. Erythema, and even eczema and sometimes boils, developed after using the water. A glassful, gradually increased to two glassfuls, might be taken before meals, but the dose must vary according to the wish for a tonic, diuretic, or cathartic effect.

The Report of the Virginia State Board of Medical Examiners was read by Dr. W. C. Dabney, of Charlottesville, President of the Board, who said that thirty-two candidates had passed satisfactory examinations since January 1, 1885, and had been licensed to practice in Virginia. Six had been rejected. All of the candidates were college graduates.

Wednesday's Proceedings.

The Annual Address was delivered by the president, Dr. S. K. Jackson, of Norfolk. He considered his elevation to the highest office in the gift of the society as an evidence of appreciation of his work in prophylaxis as applied to zymotic diseases. The hindrances to the rapid progress of the science of medicine, the most important factors in its recent development, and the most potent agencies to be invoked to secure its continued growth were also considered.

Scarlet Fever was the subject announced for general discussion, which was opened by Dr. Thomas J. Moore, of Richmond, who said that he adopted the customary divisions, such as scarlatina simplex, scarlatina anginosa, and scarlatina maligna. He gave graphic descriptions of each form, and traced the history of the disease from its earliest mention down to the present day. He discussed the origin of the fever, and laid much stress upon the germ theory. The success in cultivating and inoculating the special microbes of charbon, chicken cholera, murrain, and other diseases in the lower animals, with modification of symptoms and abatement in the severity of the

respective diseases, was described, and the hope expressed that corresponding advances in human parasitology might follow close in its wake. He stated that up to the present time the only germ that had filled all the necessary requirements, as found in man, through inoculation and otherwise, was the *spiro bacterium* of relapsing fever found by Obermeier and called after him. The parallelism between small-pox and charbon was alluded to, traveling, however, in opposite directions—the one from man to the lower animals, the other from the domestic animals to man; the special bacillus of the latter had been discovered; through cultivation and inoculation it fulfilled all the law required of it; like vaccination in small-pox, it produced, through inoculation of a remote culture from the virus of one of the lower animals, immunity in the human family; the peculiar microbe producing the former had not yet been determined; he hoped that it would come to light at no distant day. Further, he stated that there were two microbes described as giving origin to scarlatina—the *monas scarlatinosum* of Klebs, the *plox scindens* of Eklund, of Stockholm. Each was ingeniously and plausibly put forward as the true bacillus. Klebs did not indulge in the enthusiasm peculiar to his confidence, while Eklund endeavored to demonstrate the absolutism of his proposition.

Dr. Moore did not think that belladonna possessed prophylactic powers, and declared it to be an indifferent drug when used to mitigate symptoms during the process of the disease. For the reduction of temperature he preferred the ice-cap to the head, rubber bag over the front of the neck and covering the great vessels, conjoined with sponging; failing in this, he used wet sheet, then cold pack, and, as a last resort, the cold bath as described by Ziemssen. He never feared the depressing effects of cold water, as patients could always be relieved from impending congestion by free resort to alcoholic stimulation. His favorite internal antipyretic up to this time was quinine—administered by rectum or hypodermically where the stomach was irritable; he hoped much from resorcin, and urged his brethren to try it and give to the world their clinical experience. The drug was safe, certain in action, a germ-destroyer. As an unguent, especially where itching and burning were prominent symptoms, he knew nothing equal to a combination of glycerin, borax, and carbolic acid. He recommended sprays as the most efficacious manner of applying internal medication to the throat, and called especial attention to the value of hydrate of chloral, two to four grains to the ounce, as invaluable for antiseptic and anodyne powers. The doctor recommended the use of small doses of mercury for a few days as an adjuvant to diuresis, in the dropsy attending acute desquamative nephritis, where diuretics were not accomplishing the desired end. Failing with these, a resort to hydragogue cathartics was indispensable. Nutritious food from the commencement of an attack, and free stimulation in all cases where the vital powers were depressed, he regarded as indispensable.

Election of Officers.—At the afternoon session the following-named gentlemen were elected officers for the ensuing year: Dr. John S. Apperson, of Town House, President; Dr. T. B. Greer, of Rocky Mount, and Dr. H. M. D. Martin, of Fredericksburg, Vice-Presidents; Dr. Landon B. Edwards, of Richmond, Recording Secretary; Dr. R. T. Styll, of Richmond, Treasurer; Dr. Hugh T. Nelson, of Charlottesville, to deliver the "Address to the Public and to the Profession" in 1886; Dr. Thomas J. Moore, of Richmond, Examiner-at-large on the State Board of Medical Examiners; Dr. Hugh M. Taylor, of Richmond, Examiner from the Third District; Dr. Meade C. Kemper, of Norfolk, Examiner from the Second District; Dr. L. Ashton, of Falmouth, to open the discussion on "Puerpera Septicæmia" in 1886. The next session will be held in Fredericksburg, in November, 1886.

The Discussion on Scarlet Fever was continued by Dr. Bedford Brown, of Alexandria, who said that he had seen malignant cases with cold extremities and tongue with a body temperature of 107° F. He used:

℞ Acid. salicylat. ..... ℥ ij;
Tinct. aconit. radicis ..... gtt. xij;
Infus. digitalis ..... ℥ jss.;
Spts. ammon. aromat. ..... ℥ iij;
Syr. aurant. cort. ..... ℥ ss.;
Aquæ ..... ℥ j.

M. S. Teaspoonful for a child five years old every three hours.

This combination reduced fever more decidedly than any other antipyretics he had used; it acted also as a diaphoretic and diuretic. A tepid bath or a wet pack increased its action. Alcoholic stimulants benefited malignant cases, tending to collapse and coma, as also cases, on the other hand, having high fever, rapid pulse, and extreme restlessness. Such agents also generally arrested adenitis. In dangerous cases, frequent baths were too exhaustive. When extensive suppuration and pyæmia threatened, tincture of iron, Fowler's solution, and quinia sulphate acted well. To arrest acute nephritis and renal dropsy, he enveloped the body with a flaxseed-meal poultice covered with oil-silk. When the kidneys were engorged, the urine bloody, with dropsy of the chest and abdomen, a full dose of calomel, followed by compound powder of jalap, would often do good. Such cases bore purgation. But if the renal dropsy was attended with cool skin, great pallor, feeble pulse and great prostration, then frequent purgation was not well borne. In such cases he used lumbar poultices, digitalis, acetate of potash, with occasional saline cathartics. A morbid element in scarlatina often developed rheumatism; hence frequent cardiac complications. When these occurred he resorted to the active agents named in the foregoing prescription. Alkalies and salines should be used in renal complications. Dr. Brown had been disappointed with the diaphoretic action of pilocarpin. Potassium iodide was often useful in nephritic sequelæ of scarlet fever.

Dr. R. I. Hicks, of Casanova, Va., had never seen anything indicating relationship between scarlet fever and diphtheria, nor had he seen scarlatinal throat complications threaten life. Mopping the throat or gargling hot water would relieve the faucial troubles. He thought the best treatment of scarlet fever consisted in cold sponging the body, and the use of quinine and small doses of carbolate of iodine internally.

Dr. Alexander Harris, of Jeffersonton, Va., emphasized (1) the benefit of isolation, both to prevent and to cure scarlet fever; (2) sick-rooms with open fire-places; (3) the bed should be out from a corner of the room, and draughts of fresh air should keep the room ventilated; (4) the patient's and the bed clothing should be daily changed; (5) the popular disinfectants were not useful in permissible doses. Fire or water above 212° was the best germicide. Hence burn or boil all clothing that had been about the patient. (6) Always disinfect a house in which a zymotic disease had been treated, if even a year or two previous. Pour boiling water over the floors, in the cracks, on the walls, etc. Steam would be better.

Dr. C. F. Lewis, of Clifton Forge, Va., believed in the stimulating plan of treatment, and thought digitalis helped to relieve the swelling of the throat. Sometimes he used chlorate of potash and muriated tincture of iron. He was a strong advocate of such sanitary measures as Dr. Hicks and Dr. Harris had just mentioned. He fed liberally.

Dr. John F. Winn, of Richmond, agreed with the speakers as to their sanitary recommendations. He thought, in towns

especially, placards should be placed on doors of infected houses as warnings to comers-in. Public funerals in all cases of death by zymotic disease should be prohibited by law. In the sick-room, old cloths, etc., should be used, which might be destroyed by fire. The popular "disinfectant solution" of copperas was not a disinfectant, but was antiseptic. Four ounces of chloride of lime dissolved in a gallon of water was a good preparation to pour over the evacuations of typhoid patients. Corrosive sublimate in solution was also used. Let all articles that were to be used again be kept immersed in one or the other of these solutions for several hours. To disinfect a room, burn in it from two to four pounds of common sulphur, with closed doors. If the body after death was to be moved, it should be kept wrapped in cloths wet with Labarraque's solution—℥ iv to the gallon.

Dr. L. Lankford, of Bowers, Va., agreed with the speakers as to the importance of fresh air in the treatment of scarlet fever, and thought that malignancy would be rare if this were more insisted upon than it was. As an illustration, he mentioned the cases of two of his children. The younger was kept down-stairs in a warm room, with the doors closed, and malignancy developed; the other child was kept up-stairs, where there was no fire and where a window was kept open, and no malignant sign or symptom developed. The weather was cold.

Dr. J. Herbert Claiborne, of Petersburg, Va., spoke of a case in his practice in which the dermic inflammation was so intense that on the third day the skin came off in large patches all over the body. Some children played day after day in the room with the patient, and yet none of them contracted the disease. Shortly afterward some other children had the fever so mildly that they could not be retained in the house; but in a short while the disease developed in some of their playmates. An old lady living in the house with these mild cases had scarlet fever so severely that she came near dying. To disinfect a sick-room, not only the organic germs must be destroyed, but the spores also. A solution of corrosive sublimate (1 to 1,000) was required to kill the spores, or water at 280°. But the best disinfectant for a sick-room after all was pure fresh air. The doors and windows should be left open. Of course always disinfect articles of clothing, etc. He thought Squibb's solution of chlorinated soda—℥ ij to the gallon of water—was the most perfect insecticide in the market, and it was cheap enough to be within the reach of all.

Dr. William L. Robinson, of Danville, Va., believed that a great deal of good resulted from proper medicinal treatment. He reduced the fever by using a full bath at 95°, which he allowed to cool down to 85° while the patient was in it. Before taking him out of the bath he gave a weak toddy, and rubbed the body over with camphorated oil before he was put to bed. He depended very much upon the free use of lithia water as a drink. If the nose got stopped up so as to compel mouth-breathing, the child waked up often from cat-naps with screams. For this condition he used the steam atomizer—two grains of chloral hydrate in an ounce of water. This kept the nose moist. Large doses of calomel and jalap should be used if kidney complications supervene. In one case of œdema of the lungs the hypodermic use of pilocarpin saved the patient.

Dr. Winn stated that a recent correspondent in the "Journal of the American Medical Association" placed his diphtheritic patients on house-tops or on the porches, and said that all got well. The more fresh air, the better were the results of treatment.

Dr. W. W. Parker, of Richmond, Va., had often been disheartened at the results of treatment of scarlet fever. Many cases, it is true, got well without any special treatment; but, until of late years, other cases did not get well under any plan. Now, however, he had better results, and he thought the best remedy for malignant cases was alcohol in free doses. He kept his patients hot. He obtained the suggestion from the good effects of alcohol in typhoid fever. Applications of turpentine were as good for the sore throat as carbolic acid. Keep the child in the house, according to the weather. In the summer the patient might go out in ten days; but in winter wait three or four weeks.

Dr. M. A. Wilson, of New River Depot, Va., had used Bartholow's tincture-of-belladonna prescription, to antagonize that condition of the throat which caused exudation, with great satisfaction.

Dr. Hugh T. Nelson, of Charlottesville, Va., thought patients often succumbed to accumulations of heat around the nerve-centers; hence the necessity for diaphoretics and heart stimulants. Afterward tonics should be used.

Dr. S. K. Jackson, Dr. R. S. Lewis, of Culpepper, Dr. W. L. Broaddus, of Newtown, Dr. John Grammer, of Halifax Court-House, and Dr. W. D. Cooper, of Morrisville—all spoke in the highest terms of Watson's chlorine treatment as described in his work on "Practice of Physic."

The Report on Chemistry, Materia Medica, and Therapeutics was made by Dr. M. G. Ellzey, of Washington, D. C., who first considered the position of chemistry in medical schools. The report advocated the demand for proficiency in elementary chemistry in medical students before matriculating, and then teaching them practical chemistry, as urinalysis, toxicology, etc. In materia medica and therapeutics cocaine and antipyrin were alluded to. No germicide could be safely applied to an absorbing surface. In climatology, Dr. Ellzey thought the Appalachian portion of Virginia the best of sanitariums for summer and fall. For the year round the climate of southern North Carolina and northern South Carolina was the best. The average amount of carbonic acid in a European atmosphere was about 4 to 10,000, whereas at Washington, D. C., it was 3 to 10,000 parts. The pyrogallic-acid tests of the percentage of oxygen in the air at Washington showed a close coincidence with European air—about 20·70 per cent. for out-door air. He thought a rich harvest awaited climatological-therapeutical studies in the near future.

The Report on Advances in Obstetrics and Diseases of Women and Children was presented by the chairman of the committee, Dr. Smelt W. Dickinson, of Marion, Va. He called attention to the changes in practice during the year regarding antiseptic midwifery. Intra-uterine post-partum injections with even weak solutions of corrosive mercury were, he thought, dangerous. The parts should be kept clean. The important thing was to render aseptic everything that entered the vagina—the hands, sponges, instruments, etc. The readiest way to effect post-partum drainage was to place the patient upon the chamber-pot, if her strength allowed, when she wanted to urinate, etc. He thought the contagium of puerperal fever was of a material nature, capable of being washed away or destroyed by antiseptic injections. If the discharges became offensive and the body temperature rose above 100° F. without plain cause, resort should be immediately had to antiseptic washes. In answer to the question, How long before a doctor in attendance upon a puerperal-fever patient might safely attend another delivery? Dr. Dickinson said the weight of opinion was that he might safely do so at once *provided* he thoroughly antisepticized himself and clothing. Extra-uterine pregnancy might be treated by killing the fœtus by electricity and then performing laparotomy. Combined version in placenta prævia was now the approved plan, and was thus executed: The vagina was tamponed so as to obtain sufficient dilatability. The patient was then anæsthetized; the hand was passed into the vagina and two

fingers inserted through the presenting placenta and the fœtus drawn to one side, while the other hand, on the abdomen, pressed the child so as to carry its buttocks down until a foot could be reached. The foot was drawn through the cervix so that the breech might act as a tampon on the lower segment of the uterus. Then spontaneous delivery was awaited, or for sufficient dilatability of the cervix to permit delivery. Credé and Weber preferred absorbent cotton as a daily dressing for the cord, which, they claimed, prevented umbilical inflammation. Ethyl-bromide promised well as an obstetric anæsthetic. Cocaine was *sub judice*. Obstetric forceps were invaluable. Abortion should be produced when danger threatened. The temperature of the *lying-in room* should be well regulated. Swinging the body was advocated as a substitute for artificial respiration.

Of diseases of women, neurasthenia was the most common, and all that Dr. Weir Mitchell had said about it—both as to cause and treatment—was indorsed. Operative interference with lacerations of the cervix uteri was now opposed, as the lacerations healed well if left to themselves. Alexander's operation for backward uterine displacements was described. Dr. Goodell preferred rapid dilatation of the cervix uteri for dysmenorrhœa of an organic nature, and also for nervous dysmenorrhœa.

In diseases of children, he remarked upon the advantage of large doses of carbonate of ammonia for scarlatina. Dr. Huffard, of Smyth County, Va., depended on the carbonate later in the disease, when languid capillary circulation set in. Bismuth subnitrate was recommended to be powdered over the sore tongue which usually occurred about the fifth day—just as in cancrum oris. Trypsin in spray form every fifteen minutes or more, if the patient's strength would permit the operations, was a solvent of diphtheritic membrane. *Chlorate of potash* should be avoided in febrile diseases where the blood was alkaline, as in diphtheria, nephritic affections with scanty urine, in uræmia, etc. Incomplete closure of the ductus venosus was thought to be the cause of icterus neonatorum. Dr. Marion Sims's view that trismus nascentium was due to "an inward displacement of the occipital bone" was supported by Dr. Hartigan, of Washington, D. C.

(*To be concluded.*)

AMERICAN GYNÆCOLOGICAL SOCIETY.

Tenth Annual Meeting, held at Washington, Tuesday, Wednesday, and Thursday, September 22, 23, and 24, 1885.

(*Concluded from page 357.*)

The President, Dr. William T. Howard, of Baltimore, in the Chair.

Wednesday's Proceedings.

The President's Annual Address.—The President read his annual address. It was entitled "Two Rare Cases in Abdominal Surgery."

Case I.—S. H., a negress, aged twenty-four years, married, presented herself at the dispensary of the University of Maryland April 20, 1882. She was seen by the clinical assistant and the following notes were made: Menstruation appeared at the age of fourteen, and had been regular and normal. She was the mother of five children, the youngest of which was two months old. She had never had a miscarriage. Some days after delivery she noticed an enlargement in the lower portion of the abdomen, which gradually extended in the middle line until it reached the umbilicus, and was attended with bearing-down pains and frequent micturition. On examination, fluctuation was found well marked all over the abdomen, with decided resonance about the umbilicus. There was dullness on percussion and there was bulging in both flanks. Six weeks later she returned to the dispensary, and at this time the resonance at the umbilicus had disappeared and the umbilicus projected. The author saw her for the first time two weeks after this observation was made. She was then quite sick, the temperature being 102° F., the pulse 132, and the respiration 32. Examination showed the presence of fluid in the pleural sac. There were also some crackling râles. The abdomen was as large as at the seventh month of pregnancy and was remarkably protuberant in the center. There was complete dullness over the entire abdomen, not changed by change of position. There was no evidence of a solid tumor, but it had every appearance of a simple unilocular cyst. Vaginal examination showed the uterus well in front of the tumor, and the sound gave a measurement of two inches and three quarters. The question which arose was as to the nature of this tumor. Was it ovarian? The extreme infrequency of ovarian tumors in the negro race was against this view. The rapid growth of the tumor was also opposed to it. The next affection considered was fibro-cystic tumor of the uterus. This was exceedingly rare. The speaker had seen but one such case in the negro. In that case the cyst was filled with pus. The patient was operated upon with a fatal result. Such tumors were rare before the age of thirty-five. They usually developed slowly. There was no menstrual disturbance in this case. For these reasons, fibro-cystic tumor was excluded. Was it a parovarian cyst? These usually developed even more slowly than ovarian cysts. They were usually flaccid, contained a thin liquid, were comparatively rare, and did not affect the general health. This was therefore excluded. It was certainly not a case of simple ascites, but was it a case of encysted dropsy of the peritonæum, so called, resulting from simple peritonitis? This was an extremely rare affection, and in the early stages there were symptoms of constitutional disturbance; the abdomen was not prominent and often it was flaccid. Encysted dropsy was excluded. Finally, on June 20th, he aspirated the cyst under antiseptic precautions. The fluid which escaped was of a light straw-color and coagulated as speedily as blood. After aspiration, large masses were readily felt through the abdominal wall. The character of the fluid corresponded with that which was said to characterize fibro-cystic tumors of the uterus. The speaker had, however, seen other cases which showed that the character of the fluid was not pathognomonic. In one case of abdominal tumor, fluid was removed which did not coagulate even after being kept for many days. The abdomen was subsequently opened and a fibro-cystic tumor found. In a case of supposed ascites in a man, aspiration was performed and the fluid removed coagulated quite rapidly.

After the cyst was aspirated the patient did well for three days, when acute peritonitis supervened and she died on the seventh day. At the autopsy a mass as large as a child's head was found in the abdomen. This consisted of omentum, the transverse colon, and small intestine bound together by inflammatory exudation. The inflamed peritonæum was invaded everywhere with miliary tubercles. There was no ovarian or uterine disease. There was some tubercular ulceration of the small intestine; the other abdominal organs were not affected. The pleura was also invaded with scattered miliary tubercles. In both lungs there were some tubercles.

This, then, was a case of encysted tubercular peritonitis simulating ovarian or parovarian cyst. The failure to recognize the true condition was ascribed to want of attention to the previous history of the case and the non-recognition of the fact that there had been free fluid in the peritoneal cavity at the first visit.

The speaker then referred to the few similar cases which

had been reported. In these cases the disease had appeared as a rule under the age of twenty-five years. It had progressed rapidly, the length of time varying from six weeks to eight months.

Case II.—F. R., aged twenty-four, was admitted to the hospital in July, 1883. She professed to belong to the colored race, but looked much like a white woman. She had been married a year, but had never been pregnant. There was no evidence of uterine disease. The abdomen was much enlarged, measuring forty-seven inches just below the umbilicus. Vaginal examination showed the uterus pushed forward by a sac containing fluid. There was apparently an immense unilocular sac. This had been first noticed seven or eight years before. The increase in size had been gradual and unaccompanied with pain. As to diagnosis, ascites was dismissed both on account of the physical signs and the absence of any cause to account for such a condition. The length of time which the affection had lasted was against its ovarian origin. There were, however, exceptional cases in which an ovarian tumor might be present for a number of years, even as many as twenty-four, without requiring operation. The age of the patient, the length of time which the cyst had been present, the marked fluctuation, and the flaccid nature of the tumor, were in favor of a parovarian cyst. There was one point against this diagnosis, and that was that, although the cyst was flaccid, it could not be compressed below the umbilicus. Fibro-cystic tumor was readily excluded. The history of the case was against the existence of encysted peritonitis. The balance of evidence seemed to be in favor of an ovarian or parovarian cyst.

On July 13th the operation was performed. It was done largely with the view of exploration. The peritonæum was found much thickened and closely adherent to the sac. With difficulty the adhesions were separated for a short distance, and the cyst presented the appearance of an ovarian cyst. A trocar was introduced and forty pounds of a greenish, viscid fluid were removed. An endeavor was made to enucleate the cyst, but the adhesions were so extensive that this could not be accomplished. The cyst was then incised to the extent of the abdominal opening, and, on looking into it, it appeared to occupy the whole abdominal cavity, stretching tightly over the spinal column. A small portion of the wall of the cyst was removed, a drainage-tube introduced, and the opening closed with stitches. Peritonitis ensued and the patient died. A post-mortem was made, but, owing to the speaker's unavoidable absence, was not sufficiently full to throw any more light upon the case than had been obtained at the operation. The nature of the cyst therefore remained unsettled.

Dr. T. A. Emmet, of New York, said that the older he got, and the more experience he had, the more uncertain he was about diagnosis. When a woman had an abdominal tumor he favored opening the abdomen to make the diagnosis, because she had something which must come out. As to rapidity of development, it could not be depended upon. He had seen parovarian cysts develop in six weeks; he had also seen cases which had lasted twenty-three years. About two years ago he saw a case in which he could not make a diagnosis. The abdomen was opened and just such a cavity as had been described was found. It seemed as though a cyst had at some time ruptured and its contents had become encysted. The cavity was left open and frequently washed out. In six weeks its size had greatly diminished. Unfortunately, the patient died at this time from strangulation of the small intestine.

Dr. William Goodell, of Philadelphia, said that he had removed tumors the nature of which he did not know to this day. In one case he worked for forty-five minutes before finding out what the tumor was. It turned out to be two ovarian tumors which had coalesced, including the uterus between them. He felt more and more the necessity of performing the exploratory operation, for without this it was impossible to make a correct diagnosis in many cases. To illustrate the difficulties of diagnosis, he reported a case seen some time ago. A lady presented herself with a solid tumor of the abdomen. There were also metrorrhagia and menorrhagia. He diagnosticated fibroid tumor of the uterus, but the growth was so mobile as to suggest the possibility of a fibroid tumor of the ovary, and it was so noted at the time. An operation was not recommended. The lady went North, and her sufferings became so great that she consulted a distinguished gynæcologist, desiring an operation. The operation was performed, and a large fibroid of the ovary removed.

Dr. T. A. Reamy, of Cincinnati, wished to put on record another case in which a fatal result followed aspiration in tubercular peritonitis. The patient was a man, but the enlargement presented all the characteristics of an ovarian cyst. Death took place the second day after the removal of the fluid.

The President thought that in the majority of cases a correct diagnosis could be made. The fact that he was able in these cases to eliminate so many of the ordinary conditions which gave rise to tumors showed that we had the means of making the diagnosis generally. The object of the paper was to give an accurate account of these cases in order that it might assist others in cases of obscure abdominal tumors.

The Care of the Perinæum during Labor.—Dr. Reamy read a paper with this title. He referred to the various opinions which had been expressed on this subject. There was a general agreement as to the importance of preserving the perinæum. In certain cases, however, from anatomical and pathological conditions, laceration was almost inevitable. The author then spoke of the various methods which had been proposed, dividing them into two general classes—those which aimed to support the perinæum, and those which were used with the object of retarding the progress of the head. There was one class of authors, numerically small, who believed that the perinæum should be let alone.

The method about to be described he had adopted several years ago, and it had given him much satisfaction. He was persuaded that he had saved many perinea by its use. It was recommended for primiparæ and others where the structures were greatly imperiled. During the early part of the second stage the patient was allowed to assume any position she preferred, but, when the head began to distend the perinæum, she was placed across the bed with the limbs in the lithotomy position with the exception that the knees were kept close together. This was important. The limbs were held in that position by two assistants. A piece of muslin or a towel, ten inches wide and forty or fifty inches long, was carried around the buttocks of the patient and over the hemisphere produced by the bulging perinæum, with the upper edge on a level with the fourchette, and the ends were given to the assistants, who were instructed to make traction during the pains in the manner that the accoucheur might direct. The bandage must be applied smoothly. The force might be exerted in any required direction. Care must be taken, however, that the pressure was equally distributed and that the assistants did not simply pull on the middle or posterior part of the bandage while the anterior portion was left lax. In order to show that this procedure was based on good anatomical grounds, the speaker next referred to the anatomy of the perinæum, illustrating his remarks with diagrams. According to the old descriptions of the anatomy of this region, it was considered that the muscular fibers decussated in the part between the vagina and the rectum. Recent observations showed that this was not the case, but that the

fibers simply met, and a laceration of the perinæum divided no muscular fibers transversely, with the exception of those of the transversi perinæi. The fibers were simply separated. When the sphincter ani was divided, its fibers were of course divided transversely. The perinæum was prevented from laceration by the protection afforded by the tissue below and the integument. The bandage used in the way described afforded a supplementary perinæum as it were. By keeping the limbs in the position indicated we enabled nature to supply tissue for the relaxation of the perinæum. When the perinæum bulged the sulci at the sides disappeared, and the perinæum with the advancing head formed almost a hemisphere. The towel was in contact with every part of this hemisphere. The advance of the head might be retarded by making traction on the towel. Where it was accessible a narrow bed might be used with advantage, the assistants taking their positions near the head of the patient. The use of this bandage avoided any tendency to exciting expulsive efforts from reflex irritation of the perinæum as was sometimes seen where the fingers were used. It was comfortable to the patient and did not cause more exposure than other methods. The bandage might be kept on until the shoulders were born, thus avoiding rupture from this cause. In order that this method should be successful, it was important that every detail should be carried out with painstaking care. Should a rupture occur, the immediate operation should be resorted to.

Dr. M. D. Mann, of Buffalo, said that the method seemed a good one in a certain proportion of cases, but he had seen some cases where it would have been of no avail. The worst ruptures occurred in cases where, at the acme of the final expulsive pain, the woman had torn herself from the accoucheur. In such cases the use of chloroform would of course obviate the difficulty. Another objection to the method was that it required more assistance than could always be secured.

Dr. J. R. Chadwick, of Boston, thought the term "supporting the perinæum" a misnomer. What was meant was retardation of the child's head until the tissues could be sufficiently stretched to permit its passage. He always insured the slow exit of the head and did not permit it to escape during a pain. The method which he employed was to have the patient on her side, and then pass one arm over the thigh. Then, by interlocking the fingers, any desired amount of pressure could be made.

Dr. Ellwood Wilson, of Philadelphia, had tried every method suggested for the support of the perinæum, with the exception of the one just described by Dr. Reamy. His usual plan was simply to instruct the woman to keep her mouth open during a pain and pant.

Dr. Reamy, in reply to the statement of Dr. Chadwick, that supporting the perinæum was a misnomer, said that the word support meant protection or succor, and had been used in this sense. The number of assistants required had been objected to, but the importance of preventing rupture of the perinæum in the first labor was so great that, even if two or three skilled assistants were required, they should be employed. With this method the patient could not get away. An objection to the method referred to by Dr. Chadwick was that the pressure was not made over the perinæum, but over the head, and extension might be produced, causing the head to come into a bad relation to the axis of the outlet. In cases in which the head had been permitted to remain pressing on the perinæum for some time, the tissues were in a state of beginning necrosis and exceedingly friable. Even in such a case the use of the towel or bandage lessened the perils of the perinæum, and it would often be saved where otherwise it would have been torn. It could not be supported with the hand under such circumstances. If it was desired, the forceps might be applied with the bandage in position.

A Case of Cæsarean Section.—Dr. Edward W. Jenks, of Detroit, described the following case, which he had seen in consultation. The patient, aged twenty-seven, had given birth to one child five years previously without special difficulty. Two years later she received a fracture of the ilium from a building falling on her. She was taken in labor at three o'clock in the morning. The physician in attendance, finding some difficulty, tried to apply the forceps. He got one blade on without difficulty, but could not, after several trials, introduce the second blade. He sent for assistance, and the attempt to apply the forceps was again made without success. The cause of difficulty was a projecting shelf of bone at the seat of fracture. Another physician was called in and the forceps was again tried. It was then decided to perform craniotomy, which was done, but still the head could not be made to descend. Dr. Jenks was then sent for. He tried to apply the forceps to make sure that it could not be applied, and, failing, tried the cephalotribe with no better success. It was then decided to perform abdominal section. This was performed at two o'clock that night, twenty-four hours after labor began. The woman appeared to be in good condition. The placenta was found attached directly under the incision and there was alarming hæmorrhage, which, however, was quickly checked by the rapid extraction of the fœtus. The edges of the uterine incision were brought together by silk sutures and the abdominal wound was closed. The patient did well until three days after the operation, when she suddenly died. It was subsequently learned that the nurse had, in disobedience to orders, temporarily left the room, and that in her absence the patient got out of bed. She complained of feeling something give way, experienced severe pain, and died in a few hours.

Dr. A. J. C. Skene, of Brooklyn, remarked that in such cases the chances of the patient were lessened by undue efforts at delivery with the forceps. He thought that this would have been a good case for the performance of laparo-elytrotomy. It was impossible to sacrifice the child by that operation if it was performed in good time. He could hardly imagine any case where craniotomy should be performed, except possibly where the head wassoengaged in a small inferior strait that it could be extracted in no other way. Even then he was not certain that the Cæsarean section would not be the best operation.

Dr. Jenks said the operation of laparo-elytrotomy was discussed, but it did not seem to be an easy operation under the circumstances. If it had not been for the unfortunate accident in this case, the woman would probably have recovered.

The Use of Tarnier's Forceps.—Dr. Ellwood Wilson read a paper on this subject at the meeting in 1881. He had offered a number of objections to the use of this forceps. His objections had been based on theoretical grounds. The object of the present communication was to report nine cases in which he had used the forceps with decided advantage to the patient. He had therefore modified his views as before expressed. A detailed account of the nine cases in which the forceps had been used was then given. The instrument used had been Dr. Howard's modification of Tarnier's forceps.

Dr. Mann had used the Tarnier forceps for the past two years in a number of cases with, in the main, satisfactory results. In one case of deformed pelvis in which the Tarnier forceps was applied, the child was injured by it. The outer edge of one orbit had been crushed in, destroying the eye. The child was living at the time of birth, but subsequently died.

The President said that, so far as he knew, he was the first to use the Tarnier forceps successfully in America. In cases of occipito-posterior positions, the application of other forceps interfered with the rotation of the head, but with the Tarnier forceps the head was free to rotate.

Thursday's Proceedings.

A Modification of Emmet's Cervix Operation in certain Cases, with a Case.—Dr. R. Stansbury Sutton, of Pittsburgh, read a paper in which he stated that, while the operation was original so far as he was concerned, he did not profess to be the only one who had performed it. Cicatricial tissue was found to a greater or less extent in every case of lacerated cervix which had lasted for any length of time. This was especially apt to be the case where nitrate of silver had been used in the treatment. The hardened tissue might be present in both lips, or it might be limited to one lip. The patient whose case was reported was operated on June 5, 1885. She was the mother of several children. There was a double maceration of the cervix. The tissue of the anterior lip was hardened and hypertrophied, and the lip was convex from side to side and also from before backward, so that by the ordinary method of operation correct coaptation could not be effected. The tissue of the anterior lip was as hard as cartilage. Ordinary denudation of the posterior lip was sufficient, and this was made, leaving the strip of mucous membrane somewhat wider than usual. The cicatricial mass involving the anterior lip was removed from border to border, completely denuding this portion of the cervix. The parts were then brought together in the usual way, and the result was excellent. The cervical canal readily admitted a sound, and the woman menstruated without difficulty. The speaker thought that there were cases in which nothing short of the complete removal of the cicatricial tissue would be sufficient.

Dr. Goodell had resorted to this device on more than one occasion, and also to another plan on a few occasions. That was to outline the strip of mucous membrane to be left, and to dissect it from the tissues below, leaving it united at its base. The indurated tissue had then been removed and the flaps brought together. The result had been good.

Dr. Skene remarked that this was not cicatricial tissue; it was a true sclerosis—a hyperplastic, indurated tissue. This was, however, simply a question as to name. Much could be done to get rid of this tissue by preparatory treatment. But this often required too much time, and then such an operation as that proposed by Dr. Sutton came in. His plan had been to do a preliminary operation, consisting in removing a transverse wedge-shaped piece from one or both lips of the cervix, as the case might require, and then bringing the surfaces together with silk stitches. After the first day the patient could go about, and the sutures were removed in the course of a week or ten days. After the size of the cervix was reduced the ordinary operation was performed. He had done both operations at one sitting, but preferred to do them separately. One objection to the method of Dr. Sutton was that it left cicatricial tissue.

Dr. George J. Engelmann, of St. Louis, said that in old and severe cases it was impossible to retain the strip of mucous membrane. He therefore removed it. He had done this on both lips, and on some occasions had complete union, but the passage of a probe served to keep a canal open. For the last few years he had paid no attention whatsoever to this central strip. To prevent union he inserted a single piece of the carbolized-silk thread which was used in closing the opening. A probe passed a few times after the removal of the sutures would dilate the canal. The result of this operation had been good. The union, the involution, and the restoration of the health of the patient had been perfect. This operation had been done only in severe cases, and, so far as he knew, none of these patients had conceived.

Dr. Mann had tried the method described by Dr. Sutton. In only one case had it been necessary to denude both surfaces. To insure a patulous canal, he introduced a piece of small drainage-tube. The patient did well.

Dr. W. H. Baker, of Boston, thought the retention of the mucous membrane of importance. The method of Dr. Sutton, by leaving cicatricial tissue on one side of the canal, would tend to make the canal tortuous. As a rule, if the patient was properly prepared, it would not be necessary to remove this hypertrophied tissue. If this was not done, Emmet's operation could still be performed in the way described by Dr. Skene. He preferred to do both operations at the same time. It was then not necessary to introduce a suture to bring the transverse incision together. Great care should be exercised in the introduction of substances between the two flaps.

The President remarked that a few weeks before the death of Dr. Sims he had seen Dr. Harry Sims perform this operation in the presence of his father. He inserted a glass tube which fitted so loosely that it had to be retained with a plug of cotton.

Dr. Skene thought that if the denudation was practiced on both sides stenosis would certainly follow.

Inflammation of the Parotid Glands following Operations on the Female Genital Organs.—Dr. Goodell read a paper with this title. He referred first to the close relation existing between the salivary organs and the genital organs of the adult, as shown in mumps and other conditions. Parotid bubo seemed particularly apt to follow ovariotomy where septicæmia had taken place. He had seen parotid bubo once in 153 ovariotomies. This was in a greatly emaciated woman, from whom a tumor weighing eighty pounds had been removed. The patient had been twice tapped; once six weeks before the operation. The second tapping was followed by septic poison, and the operation was performed as a last resort. The patient did well until the ninth day, when the left parotid gland began to swell. It suppurated and was opened. The patient finally died on the twenty-second day after the operation.

There was a transference of irritation to the parotid glands in which there was no evidence of septic poisoning. Of this the author had seen three instances: twice after ovariotomy and once after oöphorectomy. In these cases the parotid complication did not influence the progress of the case. Not one of these ended fatally. He regarded the affection of the glands as sympathetic and not symptomatic. Within a short time he had operated on a lacerated cervix. The operation was followed by free hæmorrhage, and in the second week the parotid glands began to swell. This was succeeded by hysterical trismus, which lasted for some time. The patient recovered.

Dr. Sutton, out of twelve ovariotomies, had lost one patient, and she died with the complication referred to in the paper. The case did well until convalescence was reached, when one parotid gland began to swell. This was followed by swelling of the other gland. The temperature varied one or two degrees from the normal. There was slight diarrhœa, but no tympany, and no soreness. A number of rose-colored spots were found about the second week over the abdomen and arm. In the third week she became much worse. The glands diminished in size, but the temperature ran up and she died. He considered the case as septicæmic. Others considered it a well-marked instance of typhoid fever.

Dr. J. Taber Johnson, of Washington, had seen this complication in one case of ovariotomy, the patient dying on the sixth day.

Dr. Mann referred to three cases which he had seen. The first was a case of ovariotomy. There were distinct symptoms of septicæmia, and the patient died before the glands suppurated. The second case was one in which he had removed all the uterus above the internal os, and also the ovaries. At the

end of the first week one gland became swollen. There was little fever. The patient made a good recovery. The third case was that of a boy who had received a penetrating wound of the abdomen. Enlargement of the glands followed, but he made a good recovery.

Dr. EMMET added two cases. Once the condition followed an operation for lacerated cervix, the patient recovering. Once it followed an operation on a small vesico-vaginal fistula, the patient dying.

Dr. BAKER had seen the complication follow Tait's operation, but the patient recovered.

Dr. REAMY had had two cases, one after Tait's operation. The patient died the seventh day after operation. The second was a case of supra-vaginal hysterectomy in which the uterus and both ovaries were removed. The left gland became much enlarged, but did not suppurate. The patient recovered.

Peristalsis of the Genital Tract, and a New Theory to explain Relaxation of the Vaginal Outlet during Labor.—Dr. JAMES R. CHADWICK, of Boston, read a paper with this title. Some time ago the speaker was called to see a primipara in labor. He found the os slightly dilated and the vaginal outlet quite rigid. Returning two hours later, he found the outlet much relaxed, although the head had not escaped from the uterus. On another occasion a woman with a bleeding fibroid tumor consulted him. The examination revealed quite a small outlet. Ergot was given to check the bleeding. After that the outlet was found much relaxed; this had occurred coincidently with the occurrence of uterine contractions and the forcing down of the tumor. Further investigation of this subject had led him to the conclusion that there was a peristaltic action of the lower portion of the genital canal as well as of the Fallopian tubes, and that it was to this that the relaxation of the outlet was largely due.

Facial Paralysis in the Infant from the Use of the Obstetric Forceps.—Dr. THEOPHILUS PARVIN, of Philadelphia, read a paper on this subject. The following case was described: A well-proportioned woman, aged thirty years, had been in labor thirty-two hours, the first stage lasting twenty-four hours. The only difficulty appeared to be want of strength in the uterine contractions. The forceps was therefore applied, and the child extracted. The following day it was observed that one side of the face was paralyzed. This was especially noticeable when the child cried. There was no evidence of bruising from the forceps. The paralysis disappeared in ten days without treatment. The literature of this affection was then summarized.

Dr. ELLWOOD WILSON had met with this accident a number of times. Recovery, as a rule, had occurred spontaneously.

Dr. GOODELL had seen such cases, and in every instance the paralysis had been on the right side. He attributed this to the predominance of the left occipito-anterior and the right occipito-posterior positions. Under such circumstances, one blade of the forceps would make pressure on the nerve.

Dr. SKENE considered the differential diagnosis between facial paralysis from injury and facial paralysis from apoplexy to be of importance. Usually the diagnosis was readily made, but difficulty occurred when there was facial paralysis from injury, associated with paralysis of the arm caused by violence in delivery. He had recently seen such a case in consultation. In this case it was of great importance to complete the labor quickly, and the shoulder had been injured in delivery, so that there were facial paralysis and paralysis of the arm on the same side. At first there was no trace of contusion, but in a short time ecchymosis appeared and a favorable prognosis was given, which was verified.

Dr. W. L. RICHARDSON, of Boston, said that in most of the cases he had seen the paralysis had been on the right side. It sometimes occurred where the forceps was applied to the after-coming head.

The following papers were read by title: "The Genu-Pectoral Posture in the Prolonged Nausea and Vomiting of Pregnancy, with Cases," by Dr. H. F. Campbell, Augusta, Ga.; "A Study of an Unusual Type of Puerperal Fever," by Dr. Fordyce Barker, of New York.

A resolution expressing the sympathy of the society with Dr. Albert H. Smith, of Philadelphia, in his sickness, was offered and adopted.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

Meeting of September 10, 1885.

The Vice-President, Dr. J. HENRY C. SIMES, in the Chair.

Secondary Epithelioma.—Dr. GEORGE DOCK exhibited to the society a patient suffering from this disease and related the following history:

The case occurred in the practice of Dr. W. W. Keen, at St. Mary's Hospital, to whom Dr. Dock acknowledged his indebtedness for the opportunity of recording it.

Mary C., aged seventy years, married, born in Ireland, applied for treatment November 29, 1884. Her personal and family histories seemed to be unusually good. No traces of constitutional disease could be found. She used alcoholic liquors in moderation, and had smoked a clay pipe for the greater part of her life. Filling the right submaxillary region and extending up over the inferior maxilla was a tumor, the distinct outlines of which included a space about three inches in diameter. The lower part was very prominent, standing out as a flattened node one inch and a half in diameter and about three fourths of an inch high, the whole height of the tumor being one inch and a half. The growth was hard and immovable on the lower jaw; the surface was smooth and red, changing to a dull purple on the nodular elevation. On the summit of this growth was an opening leading upward and inward three quarters of an inch. The skin around the opening was everted and the surface of the crater-like cavity was covered with large and small granulations which exuded a thin, gray, offensive pus. The neighboring lymph-glands were not enlarged. The general condition was good.

The patient stated that the growth first appeared, six months before admission to the hospital, as a "kernel" below the jaw. She applied various poultices and salves to it. The tumor grew rapidly for the following four months, when it opened, discharging a large amount of pus; after that there was no apparent increase in size. The patient could assign no cause for the tumor except a scald, received about one year before on the lower lip near the angle of the mouth on the right side. This was followed by an ulcer, which was removed at the Episcopal Hospital in February, 1884, about two months before the appearance of the enlarged gland. Dr. J. M. Bradford, late resident physician at the Episcopal Hospital, stated that the ulcer was noted as epithelioma.

On December 3, 1884, Dr. Keen removed the tumor, together with a margin of healthy skin and the submaxillary salivary gland. The external plate of the inferior maxillary appearing roughened, it was cut away. The cavity of the mouth was not opened. By the use of hare-lip pins and sutures, the edges of the large wound, four inches and a half in diameter, were approximated almost perfectly. The dressings at first were carbolized; afterward iodoform was used. In the fourth week after the operation a small, red, indurated, sometimes painful spot appeared in the skin just posterior to the wound. A few days later the patient was discharged.

Microscopic sections, made through various parts of the

growth, showed the structure of squamous epithelioma everywhere. The salivary gland was invaded. No trace of the lymph-gland could be found, and the supposition was that it had ulcerated away completely.

The patient was lost sight of until the beginning of May, 1885. She stated that after leaving the hospital the small swelling alluded to increased rapidly in size, and in a few weeks was larger than the one removed. She used no irritating measures, but the tumor broke down and ulcerated away, leaving a large granulating surface. Examination revealed an ulcer on the side of the neck extending from one inch to the right of the median line to beyond the angle of the jaw, irregularly circular in outline and containing islands of epithelium. There was a small opening into the cavity of the mouth midway between the angle and the symphysis of the jaw and just inside of the inferior border of that bone. The symphysis was drawn to the right about half an inch. There was a hard, tender swelling on the gum above the inner edge of the opening, covered with small, dark-red nodules. In June the inferior maxilla was still more atrophied and had separated at the point of swelling and opening before mentioned. The adjacent ends of bone and gum were covered with a small fungous growth.

The process of atrophy and new growth is still continuing. The left alveolar process approaches the median line of the oral cavity, and the point of the chin is on a line dropped from the outer angle of the right eye. The ulcer on the neck is healing, but the new growth in the mouth is rapidly enlarging, so that the tongue can not be extruded. There are no enlarged lymph-glands, but within a few days the patient has complained of pain in a gland in the subclavian region. The general condition is very poor; the patient lives on liquid food and takes morphia to produce sleep.

An Enlarged Prostate.—Dr. Guy Hinsdale exhibited a specimen which had recently been presented to the Mütter Museum of the College of Physicians by Dr. J. L. Stewart, of Erie, Pa., and was removed from a man aged seventy-five years, who, sixteen years previously, had first come under Dr. Stewart's observation.

At that time he was a strong, well-developed man, who had never been sick before in his life, but was then suffering from retention of urine, which had existed for seventy-two hours. It was found to be impossible to introduce a catheter, owing to an enlarged prostate estimated to be larger than a hen's egg. Circumstances rendered it necessary to force an instrument through the gland, and five pounds and a half of urine were drawn off. A train of most unpleasant symptoms followed, and for weeks there was profuse suppuration with complete incontinence and great prostration. After about thirty days, improvement began and continued to complete recovery. Three months afterward the patient seemed perfectly well.

Attacks of cystitis and retention became frequent, and for sixteen years only once did an interval of over three months pass without an attack, the usual time being about twenty days. During this time Dr. Stewart introduced the catheter 1,194 times. Pain was intense during the later years, when four or five ounces of urine had collected in the bladder. Meantime the prostate continued to increase in size, and in November, 1884, was believed to be of the size of a large orange. On the night of the 27th of May, 1885, the patient had his last attack. Dr. Stewart not being at hand, two other physicians did not succeed in introducing an instrument. Just before 9 A. M. of the following day the man was attacked with the most excruciating pain, followed by a severe chill. At this time it is believed by his medical attendants that rupture of the bladder occurred, and the early date of this accident was accounted for as being the result of the contracted condition of the bladder. From this time there was no acute pain, but there was a severe aching followed by prostration. At 9.30 A. M. the bladder was aspirated, one ounce of urine coming away. Dr. Stewart catheterized him on the third day, drawing about a tablespoonful of urine. The patient died on the morning of the fourth day. His mind was clear and his voice strong to the last.

The post-mortem examination was not made by Dr. Stewart personally. It was stated that there was a rupture of the anterior part of the bladder near the fundus, and that the cavity of the abdomen was filled with urine. The specimens were not removed in such a way as to make this evident.

The specimen, as presented, consisted of the prostate gland laid open by a cut in the vertical line and having attached to it the bladder, the walls of which had been cut in several directions. These walls were thick and had apparently undergone fatty degeneration, as had also the kidneys which accompanied the specimen, the pelves of which were thickly overlaid with fat. The long diameter of the prostate, after being in alcohol for three months, was three inches; the shorter diameter two inches and three quarters; the third lobe was one inch long, and through it the catheter passed and still remained in position. The bladder-walls, when replaced, indicated a very small internal capacity.

Dr. J. M. Barton stated that but one case of rupture of the bladder from over-distension had come under his observation. It occurred in a German, who had an impermeable stricture of eight years' duration; no urine whatever passed; the contents of the bladder were removed several times by aspiration, while attempts were being made with filiform and other bougies to pass the stricture. As these failed, perineal section was suggested to the patient and his friends, but refused, and the doctor was told that they would send for him when they needed him. Three days later Dr. Barton was sent for; he proceeded to the house accompanied by Dr. S. W. Gross. The man was in a dying condition; the bladder tumor, which before was very prominent, had disappeared. Aspiration over the pubes, and a trocar inserted by way of the rectum, both failed to reach any urine.

On post-mortem examination, a small rent was found in the upper part of the bladder, but the specimen could not be secured.

In old cases of prostatic obstruction Dr. Barton had several times found, on post-mortem examination, that the patient had thrust the instrument through the "third" lobe; in one case several such openings had been made and had kindly healed.

Cancer of the Stomach.—The Committee on Morbid Growths reported regarding Dr. Mitchell's specimen, exhibited at the last meeting in June, as follows:

(*a*) *Stomach.*—Microscopic sections across the wall of the stomach showed an active proliferation of the epithelium of the mucous membrane, pushing its way into the wall, infiltrating it, and forming alveolar spaces. The wall was further infiltrated with young cells, which, for the most part, replaced the normal structure of the part. The process had probably been a chronic catarrh with great hypertrophy, passing gradually into a carcinomatous type.

(*b*) *Omental Nodules.*—Sections of these showed an indistinct alveolar structure filled with epithelial cells, and a small-celled infiltration of the adipose tissue. The appearances were those of a carcinoma, secondary, probably, to the growth in the stomach.

Hæmatocele of the Testicle.—The committee reported regarding Dr. Nancrede's specimen as follows:

Sections exhibited layers of more or less well-developed connective tissue, through which were scattered numerous young connective-tissue cells. No evidence of sarcoma tissue was

present. The growth should be classed as a chronic connective-tissue hypertrophy, and, as the sac contained blood, the specimen was of chronic hæmatocele.

Miscellany.

The International Medical Congress.—In addition to those heretofore mentioned in our columns, the following-named appointees are said to have declined to hold office under the new organization: President Gilman, of the Johns Hopkins University; Dr. E. Fletcher Ingals, of Chicago; and Dr. E. G. Loring, of New York.

The "Medical News" publishes the following resolutions lately passed by the Chester County, Pa., Medical Society:

"*Whereas*, The members of this society feel a lively interest in the prosperity of the American Medical Association and in the highest success of the Ninth International Medical Congress, and believe that when a mistake has been made it is better to correct it than to ignore it through a false pride of consistency; therefore

"*Resolved*, That it is the judgment of this society that, while the American Medical Association has a perfect right to enforce its code of ethics upon all associations subordinate to it, it has no such right as regards the International Medical Congress, a body with which it has no fixed connection and which does not undertake to regulate matters of professional ethics. That the attempt to organize the Congress solely from its own membership and that of subordinate associations was most unwise and inhospitable, and calculated to lessen the influence and usefulness of the American Medical Association.

"*Resolved*, That we hereby instruct our delegates to the next annual meeting of the American Medical Association to use all honorable endeavors to secure that the false step taken at New Orleans shall be retracted, and that those who led the association into the present folly shall not be intrusted with the arrangements for the International Medical Congress."

The "Louisville Medical News" says:

"On another page we quote from the Congress committee's authorized report the more important items of its doings at the recent called meeting in New York city. A careful inspection of the report shows that beyond a liberal alteration of the rule of membership, the separation of gynæcology from obstetrics, and the restoration of the section of dental and oral surgery to the place assigned it by the original committee, with fit elaboration of the rule relating to finances, no essential changes are made in the scheme of organization. The chief work of the committee seems to have been the re-arrangement of the lists of officers, committees, and councilmen, and the filling of the many gaps in the ranks made by the withdrawal of those who declined to serve under the new leaders.

"No concession was made to the wishes of the distinguished seceders and their many supporters among the profession at large, unless the retention of the name of Dr. Bowditch upon the list of vice-presidents be so construed. The only concession upon the other side was offered by Dr. S. C. Gordon, of Maine. This gentleman repented of his sin against the new committee, and, after confession, was graciously received and forgiven, but not conducted to a higher seat in the synagogue.

"It will also be noticed that the opinions of certain distinguished foreigners with reference to the committee's office and work were ignored *in toto*, not being accorded even the courtesy of a polite remonstrance. The committee has doubtless done just the work its manipulators set to its hands; but, whether its policy be voted wise or foolish, the *dénouement* will show that the breach between the opposing parties is widened beyond repair, and that the contending voices are dissonant beyond the hope of harmony.

"The distingnished guests who, soon after the June house-warming, stepped out and have since been standing in the rain, have not been asked to come in by the new proprietors; nor would they in the existing state of the house have accepted the invitation had it been extended. Their places have been or soon will be filled by others, worthy, indeed, but less renowned; and when the new list of officers and councilmen for the Ninth International Medical Congress shall be laid before the medical world, it will be destitute of many attractive features which characterized the original committee's issue in the early spring. Whether or not this strangely altered face will have charms of sufficient attractiveness to draw our foreign brethren across the sea remains to be seen; but, if the signs of the times be not grossly misleading, the Congress of 1887 will not meet on American soil."

"The Journal of the American Medical Association" says: "Perhaps the action of no organized body of men was ever before so extensively and persistently misrepresented as that of the American Medical Association at its meeting in New Orleans regarding the preliminary organization of the International Medical Congress of 1887. Instead of wasting time and space in enumerating and refuting these misrepresentations in detail, we will oppose to them all the following simple statement of historical facts:

"1. At the preceding annual meeting in Washington, May, 1884, on the recommendation of the president, Prof. Austin Flint, of New York, indorsed by the report of a special committee, of which Dr. J. S. Billings, of Washington, I. Minis Hays, of Philadelphia, and Lewis A. Sayre, of New York, were members, the association was induced to adopt resolutions presented by said special committee, authorizing the president of the association to appoint a committee of seven, of which he should be a member, which committee should attend the International Medical Congress to be held a few months later in Copenhagen, and in behalf of the *profession of the United States* extend an invitation for the next triennial meeting to be held in this country. If the invitation was accepted, the same series of resolutions conferred upon the same committee authority to add to its number and exercise all the powers of a committee of arrangements for effecting the preliminary organization of the proposed Congress, with an appropriation from the treasury of the association to defray necessary preliminary expenses. The committee thus authorized was appointed by the president and consisted of Dr. J. S. Billings, Dr. Austin Flint (*ex-officio*), Dr. I. Minis Hays, Dr. J. M. Browne, Dr. L. A. Sayre, Dr. Christopher Johnson, Dr. S. J. Engelmann, to which was added Dr. H. F. Campbell as president-elect of the association. The fact that this Committee of Invitation had been appointed by the American Medical Association, which by such appointment had made itself responsible for the acts of such committee in carrying out the instructions contained in the resolutions, was published in all the leading medical journals, and could not have been otherwise than well known in Europe. In due time the invitation was extended by the committee and formally accepted in open session of the Congress in Copenhagen. The committee returned home, invited sixteen other prominent members of the profession to unite with them, constituting a General Committee of twenty-five. This General Committee held one meeting in Washington, organized by the election of a president, vice-president, secretary-general, and treasurer. Rules were also adopted for the organization of the Congress, one of which made the officers of the committee also the general officers of the preliminary organization of the Congress. At the same meeting some of the officers of sections were appointed, and further details of the work were committed to an Executive Committee of five, subject to the approval of the General Committee. The Executive Committee, by conferences of its own and by correspondence with other members, so far completed the work of organization as to publish the results both in this country and Europe only a few weeks before the annual meeting of the association in New Orleans, the last week in April, 1885.

"2. At the meeting of the association in New Orleans, Dr. J. S. Billings, as the secretary-general of the proposed Congress, made a brief report of the doings of the committee and presented a printed copy of the rules and official organization adopted. The report was received and made the special order for consideration the following day. At the hour appointed, several members freely criticised the work of the committee, pointing out the fact that it had appropriated all the chief offices of the Congress to its own members, that it had centered an unduly large proportion of the officers of sections in two or three cities, instead of making them representative of the profession of the United States, in whose name the invitation had been given, and had given undue prominence to a particular portion of the profession in

New York, which was well known to have arrayed itself in opposition to the State and national organizations of the profession generally. The result of the discussion was the adoption of two resolutions by the association, both of which have been repeatedly published in the columns of this journal, the effect of which was clearly to make the Committee on Organization more national in character, or, in other words, more directly representative of the profession of the United States, by adding to the original committee of eight, one from the profession of each State and Territory, in the place of the additions previously made by the original committee, and to give the committee thus enlarged authority to review the work previously done by the Committee on Organization, and make such changes as the enlarged committee might think advisable. This was the sum total of the action of the American Medical Association concerning the organization of the Congress. The resolutions adopted contain not one word about codes of ethics, they displace no one of the original committee, they prescribe no rule either for the membership, government, or officering of the Congress, but simply enlarge the original committee in such a way as to make it more representative of the whole profession, and continue in the enlarged committee the same powers, substantially, as were conferred upon the original committee at the meeting in Washington.

"3. The committee as enlarged by the action of the association in New Orleans held its first meeting in Chicago, June 24 and 25, 1885, and organized simply as a committee of arrangements, its officers having no corresponding positions in the proposed Congress, as had been the case with the first organization of the committee. After as full an examination of the work previously done as the time would permit, the committee re-adopted nearly all the rules previously devised except those relating to the American membership and the Executive Committee of the Congress. The first of these it was proposed to amend in such a way as to unnecessarily restrict the membership, and all provision for the latter was overlooked. In consequence of these defects, the proper work of the committee was continued, and a second general meeting held in New York, September 3 and 4, 1885, during which the revision of the rules was completed, the vacancies in the general offices of the preliminary organization of the Congress filled, and an executive committee provided for, consisting of the president of the Congress, the secretary-general, the treasurer, the chairman of the finance committee, and the presidents of the several sections. The Committee of Arrangements thus deliberately completed the work assigned to it by the association, and delegated to the Executive Committee of the Congress full power to fill all future vacancies, complete all unfinished details of organization, increase to a limited extent the number of its own members, and manage all the affairs of the Congress in accordance with the rules adopted, without other restraint or interference from any source. The rules in detail, together with the general officers of the Congress, the presidents of sections, and the Executive Committee, were published in this journal for September 12, 1885.

"We have given the foregoing plain narrative of facts regarding the action of the American Medical Association and its Committee of Arrangements for providing a preliminary organization for the International Medical Congress of 1887, which would fairly represent the medical profession of the United States, and under rules as liberal, in relation to membership and in all other respects, as those adopted by previous Congresses, to show, first, how utterly groundless have been the charges and denunciations so persistently hurled at the association and its committee; and, second, that, notwithstanding all the persistent opposition of a few prominent members of the profession having control of three or four leading medical journals, the association, through its enlarged and representative committee, has fulfilled the obligations it incurred in inviting the Congress to hold its next meeting in the City of Washington in 1887, by effecting a preliminary organization on a national and liberal basis, with ample power to manage all the business and scientific interests of the Congress as independently as the interests of any previous Congress has been managed in Europe. The responsibility is now with the new Executive Committee and the true friends of the Congress everywhere. If the committee will take up its work promptly and push it harmoniously, it will receive ample support both at home and abroad, and the Congress will be as successful as the most enthusiastic could desire."

The "Medical Times and Gazette" says:

"A few days after the earliest news of the danger threatening the next International Medical Congress had been published in Europe ("Medical Times," July 11 and 18, 1885), the two most prominent officers of the London Congress, Sir James Paget and Sir William MacCormac, each wrote to an American friend to express their view of the situation—a view which coincided in all particulars with that previously given vent to in our columns. These letters were not merely an expression of individual opinion, but were the result of consultation with several of the most influential members of the London Congress. Sir James Paget, in giving his recollection of what took place at Copenhagen when the American invitation was accepted, writes: 'Certainly it was not supposed that the Congress would be regulated with any degree of exclusiveness by the members of one medical association, however numerous, and I think it quite as certain that, if this had been thought possible, the proposal that the next meeting should be held in the United States would not have been adopted.' 'I am sorry, also,' he adds, 'to feel sure that, if the Congress be not supported by the eminent men who have now declared that they will take no part in it, the members of the profession in this country who attend it will be very few.' Sir William MacCormac, in his account of what happened at Copenhagen, says: 'I am sure it was present to the mind of every one there that the invitation was one from the profession of America, and not from any section of it, or any particular medical society in it. Otherwise, I feel pretty certain Prof. Virchow's invitation to meet on the next occasion in Berlin would have been accepted.' In our last issue we published what may, we suppose, be called the official reply to Sir W. MacCormac's letter. In it, Dr. Davis, the editor of the 'Journal of the American Medical Association,' censures with some bitterness those Americans who have 'a morbid tendency to hang their laundry on the front street,' and complains that so much attention should have been given to 'this little misunderstanding' by European medical journals. Possibly some of the readers of those journals may sympathize with that complaint, but, as the welfare of the next International Medical Congress is not a matter solely of American interest, it seems to us to have been the bounden duty of individual men in Europe, and of the European medical press generally, to point out to what extent the organizers of the Washington Congress were departing from the established precedent, which, at any rate, has the argument of unbroken success in its favor. Dr. Davis complains that 'the outside world' animadverted on the conduct of the American Medical Association before hearing both sides of the question. It may be replied to that complaint, first, that the action of the association in disregarding the precedent of previous congresses, and monopolizing the conduct of the Washington meeting, was in itself a sufficiently accomplished fact to warrant any amount of European animadversion; secondly, that the subsequent action and arguments of the supporters of the association have served rather to weaken than to strengthen their case; and, thirdly, that it may be fairly assumed that the publication of European criticisms has had a measurable share in determining the new Committee of Organization to reconsider the whole question at issue during the present month, instead of deferring it, as originally intended, until next spring.

"We may remind our readers that two main objections have been raised to the action of the American association—first, that, contrary to precedent, the association put itself forward as the sole and exclusive organizer of the Congress; and, secondly, that, equally contrary to precedent, it determined that only its own members, or delegates from the societies in affiliation with it, should be allowed to take part in the Congress. We are glad to hear that the latter objection has been founded on a misconception, and that the conditions of membership were still under consideration, and were not to be finally settled until the 3d of this month. We hoped to have been able to give our readers information as to the result of the meeting at which this point was to come on for consideration, but up to the time of going to press we have received no report of the proceedings. We trust, however, that the more liberal views which have governed the admission of members at previous congresses will have prevailed, and, if so, it may, we think, be safely claimed that the opportune advice of Sir James Paget, Sir William MacCormac, and the European journals has had some share in the result.

"But the objection still remains that the American association, in taking charge of the Washington Congress, has introduced an innovation in the conduct of International Medical Congresses which is distinctly a matter for international criticism, and, in our deliberate opinion, for international condemnation. One of the most representative medical men in the United States, who had been looked to by the new Committee of Organization as a possible successor to Dr. Billings in the office of Secretary-General of the Congress, Dr. Packard, of Philadelphia, has stated it as his conviction 'that it is contrary to all precedent for the American Medical Association to assume any control of the management of the Congress, which is a body by itself, and the members of which will be in no sense the guests of the association, or subject to it.' 'Were I Secretary-General of the Congress,' he adds, 'I should not consider myself the appointee of the American Medical Association, nor responsible to it in any degree.' We believe that all the officers of past congresses will fully sympathize with Dr. Packard in this candid expression of opinion, even though it implies the condemnation of the action of the original organizing committee which first raised the whole question and gave itself over, bound hand and foot, to the American Medical Association, by admitting its responsibility to it. That the original committee acted with great lack of judgment, first, by a too lavish distribution of offices among themselves, and secondly by reporting to the association, is now, we believe, generally admitted. On this technical point no doubt the advocates of the association have the best of the argument. But they have as yet proved no vestige of a right on the part of the association to break through the rule of previous congresses, and to assume the sole management of the Congress of 1887. Dr. Davis's argument, that 'as there is only one body in England representative of the whole English or British profession, the British Medical Association, so there is only one in the United States which could under any possible circumstances represent the profession in the United States, viz., the American Medical Association,' is ludicrous rather than convincing to the English or British reader, especially when the wise self-effacement of our own association at the time of the London Congress is borne in mind.

"But the further action of the American association proves better than anything how wise has been the precedent of previous congresses, and how ill-advised the attempt to break through it. One of the first acts of the American Medical Association, when it got hold of the Congress, was to insist that only those in accord with the National Code of Ethics should become officers of the Washington meeting, and, as a result of this, many practitioners whose names are household words to us, and who are described by Dr. Noyes in a published letter as 'the brightest lights and best workers in the profession,' have been expelled from all official connection with the Congress. By that action the association at once broke the pledge deliberately given at Copenhagen, relit the old-code dispute, and attempted to score a point against the 'new-coders' by enlisting against them the European visitors to the Congress. The full and final results of this policy have yet to be seen, but its first fruits, in the form of an electioneering manifesto published by the association and sent to us by its representative, Dr. Shoemaker, are not particularly reassuring. This manifesto is headed, *more Americano*, 'PENNSYLVANIA SUSTAINS THE CODE OF ETHICS,' and then follows a long list of practitioners in that State, all of whom profess to heartily indorse the action of the association in raising the code question. We need hardly add that this single official leaflet will do more to deter respectable English practitioners from taking part in the Washington Congress than all 'the statements of certain medical journals and private parties in Philadelphia and New York,' of which Dr. Davis so bitterly complains in his letter to Sir W. MacCormac. In our opinion, the time has now come for the officers of past International Medical Congresses to meet together and decide that, unless the pledge given at Copenhagen is kept, and all attempts to embroil the Congress in ethical disputes are unconditionally given up, the acceptance of the invitation to meet at Washington should be rescinded, and arrangements made to hold the Congress of 1887 in a country where the medical profession possesses greater solidarity."

The "Medical Times and Gazette," of London, publishes the following letter addressed by Dr. N. S. Davis to Sir William MacCormac:

"Having just read in the 'Boston Medical and Surgical Journal,' of August 13th, your letter to Dr. J. Collins Warren regarding the International Medical Congress, I feel that it is incumbent upon me to reply to it personally, not only on the part of the medical profession of the United States, but also on the part of the American Medical Association; and also on account of your manifest misapprehension of the 'serious disagreement' of which you speak in your letter. *Imprimis*, I will say that everything that has as yet been said by the European press generally, and by the letters of individual men in Europe, bears the evidence of misapprehension and misinformation. Our foreign *confrères* have accepted, unreservedly, the statements of certain medical journals and private parties in Philadelphia and New York, who from the very first of this little misunderstanding (which should be a private affair until it is definitely settled in one way or the other) have endeavored to obstruct the Committee of Arrangements for the Ninth International Medical Congress. I have said that it should be a private affair until it is definitely settled. It is unfortunate that some Americans have a morbid tendency to hang their laundry on the front street, where each passer-by may tell at a glance the character and extent of his neighbor's wardrobe. But still, it ill becomes his neighbor to tell it to the world; still less does it become the outside world to animadvert on it before hearing both sides of the question. The profession in Europe seem to have heard of this matter from one side only, and, without being conversant with the facts, have hastily jumped to very illogical conclusions. As there is only one body in England representative of the whole English or British profession—the British Medical Association—so there is only one in the United States which could, under any possible circumstances, represent the profession in the United States—and that is the American Medical Association. From Maine to California, and from the British possessions on the north to Mexico on the south, every State and Territory is represented in that body. Now, you say in your letter that you are 'sure that it was present to the mind of every one there (Copenhagen) that the invitation (to have the Congress meet in Washington in 1887) was one from the profession of America, and not from any section of it, or any particular medical society in it.' To which it may be replied: The invitation was extended by Dr. Billings, and Dr. Billings had been appointed to extend the invitation. Who appointed him? Whence came his authority for assuring the Congress that it would receive a warm welcome in this country in 1887? He was one of a committee *appointed at* a meeting of the American Medical Association, *by* the president of the association, who acted *for* the association, and by the authority of the association. And the necessary funds for enabling this committee to perform their work were voted to it by the association; and they drew upon the treasurer of the association for the money. Further than this, the committee was known and recognized as the Committee of the American Medical Association on the Organization of the Ninth International Medical Congress. They themselves recognized the fact that they were the Committee of the American Medical Association, else why should they have reported to the association at its last meeting, in April, 1885? Can any one imagine a body of sane men reporting to another body to which they owe nothing, and to which they are in no way amenable? Yet, when the creator of that committee—the body to which it owed its very existence—saw fit, on just grounds, to revise a part of their work and to appoint additional members to the committee to aid in such revision, they boldly say that the association has nothing to do with it. The merest tyro in parliamentary law knows that the power which appoints a committee may refuse to accept any of the work and appoint a new committee if it see fit. That right is unquestionable, and unquestioned save by those who know not whereof they speak. The American Medical Association has invited the Congress to meet in Washington in 1887, and the invitation has been accepted. The American Medical Association is fully competent to make all necessary arrangements for that meeting on as liberal a basis as has characterized any of the preceding congresses. We only ask that our brethren in Europe will reserve their comments until the programme is completed and before them."

The editor of the "Times and Gazette" adds the following comment: "We have not space in the present number to deal fully with Dr. Davis's letter or with the other documents stating the case of the American Medical Association which have reached us. We may, how-

ever, point out here that the British Medical Association has never claimed to represent the whole English profession, though we believe its claim to do so, if it should ever be so ill-advised as to make it, would be much more valid than the claim put forward on behalf of the American Medical Association. Whatever Dr. Davis may say, the fact remains, as the officers of the London Congress have stated, that on no previous occasion has any medical body attempted to capture and run the International Congress as the American association is now attempting to do."

New York State Medical Association.—The first annual meeting of the Fifth District Branch will be held in Brooklyn, at the Mansion House, Hicks Street, at 11 A. M., on Tuesday, October 13, 1885. The following papers are expected to be read: "Suggestions in regard to the Causation and Treatment of Acute Coryza," by Dr. Austin Flint; "Further Observations on Diphtheria," by Dr. W. H. Thayer; "The Physician and the Pharmacist—their Relative Duties," by Dr. J. P. Garrish; Report of a "Case of a Railroad Accident," by Dr. W. Govan; Remarks on "The Milk Supply of Large Cities and the Improper Mode in which it is conducted," by Dr. H. A. Pooler; "Progress of Electrolysis in Surgery," by Dr. Robert Newman.

The Brooklyn Pathological Society.—The following programme for the season has been issued: October 8, 1885, "The Pathology of the Inflammatory Process," by Daniel Ayres, M. D., LL. D. October 15, 1885, "The Pathology of the Inflammatory Process" (continued), by Daniel Ayres, M. D., LL. D. October 22, 1885, "The Nervous Symptoms of So-called Lithæmia," by Landon Carter Gray, M. D. November 12, 1885, "Some Serious Sources of Error in studying the Course of Disease," by Robert G. Eccles, M. D. December 10, 1885, "On the Relations of Locomotor Ataxia to General Paresis," by E. C. Spitzka, M. D. January 14, 1886, "On Diseases of the Brain resulting from Affections of the Ear and Temporal Bone," by Arthur Mathewson, M. D. January 28, 1886, "The Relation of Modern Dietetics to the Causation of Disease," by E. H. Bartley, M. D. February 11, 1886, "The Rôle of Tubercular Infection in the Development of Surgical Diseases," by Lewis S. Pilcher, M. D. February 25, 1886, "On the Pathology of Surgical Infection," by A. H. P. Leuf, M. D. March 11, 1886, "On the Microscope in Diagnosis," by Frank Ferguson, M. D. March 25, 1886, "The Effects of Diseases of the Nasal Passages on the Lower Respiratory Tract," by Thomas R. French, M. D. April 8, 1886, "The Pathology of the Sympathetic Ganglia," by John C. Shaw, M. D. April 22, 1886, "On the Pathology of Tubercular Osteomyelitis, and its Bearing upon Treatment," by George R. Fowler, M. D. April 29, 1886, "Some Abnormalities of the Pulmonary Circulation," by Benjamin F. Westbrook, M. D. May 13, 1886, "The Pathology of the Lymphatic Glands in Children," by Henry N. Read, M. D. June 10, 1886, "The Pathology of the Puerperal Fevers," by Charles Jewett, M. D.

THERAPEUTICAL NOTES.

A Salicylate-of-Sodium Ointment.—Much of the efficacy of an unctuous preparation of salicylate of sodium depends on the way in which it is made. M. Pierre Vigier recommends the following method ("Gaz. hebdom. de méd. et de chir."):

Crystallized salicylate of sodium.....	2½ drachms;
Distilled water.....	75 grains:
Lard.....	10 drachms.

First spread the lard over the inside of a mortar, then dissolve the salicylate in the water, and add the solution little by little to the lard, triturating until the two are perfectly incorporated. The precaution of first smearing the inside of the mortar with the lard does away with the necessity of using oil of almonds, which otherwise is often found necessary.

The Treatment of Pulmonary Gangrene with Inhalations of Carbolic Acid.—M. Constantin Paul (*Ibid.*) reports seven cases in which this method of treatment was used with success. A one-to-seven watery solution is used in an inhaler so constructed as to insure the inhalation of all the vapor, while preventing the liquid from escaping. The first effect is to arrest the putrefaction of the tissues. After the sphacelated parts have been thrown off, the expectoration diminishes, fœtor ceases, the appetite revives, and recovery may take place in less than two months.

Euphorbia icterodoxa.—M. Landowsky (*Ibid.*) has studied the caustic and destructive action of the juice of the *Euphorbia icterodoxa*, a plant that grows in the neighborhood of Pernambuco, and is vulgarly called "alveloz." Although its caustic action is energetic, at the same time it produces an analgesia comparable to that caused by cocaine. The author has destroyed an epithelioma with it, but he failed in a case of cancroid. Besides its escharotic action, the juice has a digestive power like that of papain.

The Use of Tanghin in Nervous Diseases.—This ordeal poison of Madagascar, derived from the apocynaceous tree variously named by botanists *Cerbera venenifera*, *C. manghas*, *C. tanghin*, *Tanghinia venenifera*, and *T. veneniflua*, has been made the subject of experiment by M. C. E. Quinquaud (*Ibid.*). Its action on the central nervous system is specially characterized by an exaltation of the bulbo-spinal reflex activity. After a certain number of experiments on animals, M. Quinquaud administered an extract to man, in doses ranging between three quarters of a grain and a grain and a half, in various diseases, notably toxic paralyses, tremor, intestinal atony, and incontinence of urine. Satisfactory effects were obtained, but only on condition that the use of the drug was ceased as soon as the patients experienced headache, nausea, vomiting, and a certain amount of debility.

A Substitute for Adonis Vernalis.—V. Cervello ("Annal. di Chim. Med.-farm."; "Ctrlbl. f. d. ges. Therap.") considers the *Adonis cupaniana* of the Sicilian coast as capable of replacing the *A. vernalis* as a cardiac roborant in countries where the latter can not readily be obtained.

Urethane as a Hypnotic.—Dr. von Jaksch (Wien. med. Bl."; "Dtsch. Med.-Ztg.") describes urethane as the ethyl ether of carbamic acid, $NH_2CO_2C_2H_5$, a white, crystalline body, readily soluble in water, odorless, and tasting like saltpeter. In doses of from four to fifteen grains, it acts as a hypnotic, affecting chiefly the brain, without notably influencing the peripheral sensory apparatus; hence it is not an anodyne. Over all other pure hypnotics, however, it seems to have these advantages: It is very well borne; it causes absolutely no complicating effects; and the sleep it produces resembles natural sleep in every respect. The author thinks it will prove particularly serviceable among children and in cases of delirium tremens and mania.

Lantanine as a Febrifuge.—This alkaloid, extracted by Negrete from the verbenaceous plant *Lantana brasiliensis*, is recommended by Dr. E. Buiza, of Lima ("Cambio farmaceut."; "Arch. de Med. y Cirug. de los Niños"; "Courrier méd."; "Nouveaux remèdes"), as a substitute for quinine. It retards the circulation and lowers the temperature, and is tolerated by the most delicate stomachs. Intermittents that have proved rebellious to quinine have yielded to thirty grains of lantanine. As an antipyretic, it is given in doses of a grain and a half, from ten to twenty of which are administered in twenty-four hours. For intermittent fever, it should be given immediately after a paroxysm, and in ninety-five cases in a hundred the next paroxysm will not appear.

Ergotin in the Treatment of Landry's Paralysis.—Dr. Sorgenfrey, a Russian physician ("Neurol. Ctrlbl."; "Dtsch. Med.-Ztg."), relates the case of a patient, fifty-seven years old, who was attacked, about a week after exposure of his back to a drenching rain, with a sensation of heat, prostration, loss of appetite, and a sense of weight in the lower limbs. Weakness in locomotion culminated in perfect paralysis of all the limbs, dyspnœa, impeded speech, dysphagia, etc. The sensibility was normal. There was no pain. The cutaneous reflexes were present, but the patellar reflex was absent. The urine was normal; the bowels were constipated. No account is given of the electrical reaction of the muscles. Leeches to the anus, dry and wet cups to the lumbar region, cold compresses, and laxatives produced no effect, and death seemed imminent. As a last resort, the following was ordered:

Bonjean's ergotin.....	19 grains;
Cinnamon water.....	2 ounces.

A teaspoonful was given every hour, and the whole was used in the course of a night. The next morning the bulbar symptoms had disappeared, and within a week, without further medication, the patient was well.

Lectures and Addresses.

LECTURES ON ELECTRICITY IN MEDICINE,

DELIVERED AT THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF VERMONT, BURLINGTON,

BY AMBROSE L. RANNEY, M.D., NEW YORK.

(*Concluded from page 284.*)

ELECTRICITY IN DISEASES OF THE CERVICAL SYMPATHETIC, THE VASO-MOTOR SYSTEM, AND ALLIED NEUROSES.

THE CERVICAL SYMPATHETIC is undoubtedly, in rare cases, the seat of isolated morbid changes; but, as Erb remarks, these cases "constitute pathological curiosities." The morbid conditions which have been detected embrace inflammation, compression, traumatism, rheumatic conditions, etc. Such conditions may create either irritation of the sympathetic system or paralysis of its functions, or both simultaneously in different parts of the body.

Irritation of the cervical sympathetic produces pallor of the face and neck upon the affected side, with a sense of coldness in the parts. The pupils are dilated, the temporal arteries exhibit increased tension, the power of accommodation and the reaction of the pupil to light are both impaired, the eyeballs protrude slightly, and the secretion of sweat is diminished.

Paralysis of the cervical sympathetic induces the opposite conditions. The skin is red and hot, the patient suffers from a sense of heat in the skin, the pupils are contracted and exhibit normal reactions to light and accommodation of vision; the eyeball does not protrude, there are often headache and vertigo, the secretion of tears and sweat is increased, and the pulsation of the carotids is excessive.

In the electrical treatment of these opposed conditions Erb recommends stabile applications of the anode (with a strong current) until a change in the pupil is observed, if the condition of irritation exists. The same author suggests the use of the cathode with a feeble current, frequent interruptions, and occasional reversal of the poles, if the paralytic state is present. He places the "indifferent" electrode upon the spine. He also suggests applications of the wire-brush, or labile galvanic currents, to the skin of the face and neck.

To the views of this author I would urge the advantage of trying the effects of static insulation and sparks directed to the neck and face.

ANGIONEUROSES OF THE SKIN may assume one of two forms, viz., *spasm* or *paralysis*. They are most frequently observed in connection with neurasthenia and in hysterical patients. The abnormal contraction or relaxation of the vessels may cause (1) modifications in the color and the general "feel" and sensibility of the skin; (2) subjective sensations of heat, tingling, formication, etc.; (3) disturbances of perspiration; (4) awkwardness of movement of the part (especially in the hands); and (5) many reflex symptoms referable to the viscera.

Unnatural conditions of the vessels of the skin (spasm or paralysis) are most frequently observed in the upper limb, less frequently in the lower limb, and least often in the face and neck. They may be excited by a variety of causes—such as fatigue, excitement, menstrual disturbances, malaria, exposure to cold, the effects of poisons, and direct irritation of the skin itself.

I have seen the skin (especially of the fingers) made as white as chalk in some cases, and in others rendered cyanotic, by *spasm of the vessels*. The muscles of the papillæ of the skin may participate in the spasm and produce the so-called "goose-flesh" appearance. Pain, tingling, formication, partial anæsthesia, and other disturbances of the sensory apparatus may occur as sequelæ to the vascular spasm.

Paralysis of the cutaneous vessels leads to directly opposite conditions. The skin may be made intermittently or permanently red, and feel unnaturally hot and extremely sensitive. Subjects so afflicted frequently suffer from insomnia, headache, disturbed heart-action, excessive perspiration, vertigo, and other visceral manifestations of irritability.

Respecting the electrical treatment of angiospasm and angioparalysis, the general rule may be given that weak or moderate applications of faradism or galvanism to the affected part act best upon dilated vessels, and stronger currents upon those affected with spasm.

Applications of static electricity are often very beneficial to neurasthenic and hysterical subjects. Personally, I believe this method of treatment surpasses any other in its effects upon this class, although it is well to alternate with galvanism and faradism when a case proves obstinate to treatment.

When any of the methods suggested are employed, it is well to subject both the vaso-motor centers and the nerve-trunks which supply the affected regions (as well as the parts directly) to the influence of electrical currents.

NEURASTHENIA.

By this term we mean the condition of *nervous exhaustion*. It may be manifested in a variety of ways. Its symptoms will depend upon the type which exists—cerebral exhaustion or spinal exhaustion—and also upon special idiosyncrasies peculiar to the patient. No two cases exhibit identical manifestations of nervous depression. Some patients who are suffering from cerebral neurasthenia manifest its effects in the voice, others in mental disturbances. The heart's action may be alone disturbed in some cases, the stomach may give out in others, some may complain alone of muscular troubles, some may notice its effects in the eyes, some are rendered sleepless, a few complain alone of skin disturbances, and so on throughout the different parts of the entire human organism.

You can understand how these apparently discordant facts may be reconciled when you consider the fact that, by means of the brain and spinal marrow and the nerves which unite these centers to the different parts of the body, we are enabled to see, hear, taste, smell, appreciate touch, swallow, breathe, and perform voluntary muscular acts. It is by means of our nerves alone that the heart beats; the

digestive processes go on, without our knowledge or control, through the same agencies; the blood-vessels contract and dilate in accordance with the demands for blood telegraphed to the nerve-center by different organs and tissues; and every process pertaining to life is thus automatically regulated. Now it is easy to see at once how a debility of so complicated an electric mechanism as the nerve-fibers and the nerve-cells of a living animal are, can upset all or any one of the individual functions enumerated. Many of our houses are furnished to-day with electric bells by means of wires distributed in the walls. In some houses we light the gas-jets, and even the rooms themselves, by means of the same subtle fluid. When the battery becomes weak, or when the wires are disarranged or broken, what may be the results? Some of the bells may cease to ring when the button is touched, while others work properly. Perhaps the electric light may fail in some rooms and burn with its accustomed brilliancy in others. The gas-jets may not be properly ignited. So it is with the nervous apparatus of man. From the same cause one patient may have nervous dyspepsia, another sleeplessness, a third sexual debility, a fourth weakness of the eye-muscles, a fifth disturbances of the skin. It is needless to multiply illustrations.

Cerebral neurasthenia (*brain exhaustion*) may be indicated by one or more of the following symptoms: Tenderness of the scalp; pains in the head; fleeting neuralgias; sleeplessness; vertigo; a tenderness and pallor of the gums; abnormal sensitiveness of the teeth; blanching of the hair; flushings of the face; dilatation of the pupils; idiosyncrasies in regard to food and external irritation; mental depression and melancholia; defects in memory; a morbid craving for alcohol; a decrease in intellectual capacity; a buzzing or ringing in the ears; specks before the vision; abnormal and imaginary impressions of taste or smell; morbid fears of various kinds; sick headache; dryness of the skin and the mucous surfaces; weakness of the muscles; numbness in the limbs; thickness of speech; and mental excitability, irascibility, or loss of emotional control.

These symptoms, in many cases, are but the manifestations of weakness. The electric batteries of the brain (those minute organs known as the "brain-cells") are feeble or uncertain in their action. They are incapable of performing the offices for which they were created. They are not diseased (in a medical sense), but they are weak and liable to become so sooner or later. I have known sufferers of this type to be precipitated into a condition of incurability by mental alarm, excited, in some instances, by an opinion of an unfavorable kind made by physicians respecting a prospect of recovery. Again, it is well known that insanity may arise as a consequence of the loss of sleep often experienced by these subjects, and by "brooding over their symptoms," whose significance they fail to properly understand. I recall several cases where a patient was with difficulty convinced that some special type of malady was not about to attack him, because in reading a medical work his attention had been called to the significance of some special symptom which he was sure he had personally experienced. If medical students, who possess vivid imaginations, can become (as they often do) victims to imaginary diseases whose symptoms they have been studying, is it to be wondered at that the weak and highly organized sufferers from neurasthenia are especially prone to become impressed by this form of delusion?

Spinal neurasthenia (*spinal exhaustion*) signifies an exhausted state of the cells which help to form the spinal cord. The cord itself is of about the size of an ordinary lead-pencil, and is sixteen inches in length (much shorter than the backbone). It is composed of millions of nerve-cells and distinct bundles of nerves. Some of these nerves pass through it to reach the brain above, while others become united to the spinal cells and pass no farther. The cells of both the brain and spinal cord are practically electric batteries; and the nerve-fibers are the wires by which they are connected with the different organs of the body, the muscles, skin, joints, and viscera. This wonderfully constructed organ is under the control of the brain, but is capable of exerting, under certain circumstances, a control over all acts which are termed "reflex acts," because they are, to a greater or less extent, independent of the will. It serves also as a means of conduction to the brain of our perceptions of pain, temperature, and touch, and of motor impulses sent out from the brain-cells to the muscles of the limbs and body.

Now, when the cells of the spinal cord become exhausted, the symptoms produced differ markedly from those already mentioned as indicative of brain-exhaustion. Among its chief manifestations may be mentioned the following: A general tenderness of the skin to touch or pressure; tenderness along the spine or over certain limited portions of the spine; irritability of the breasts, ovaries, and the womb in females; fleeting pains of a neuralgic type in various parts of the body; an extremely rapid or slow pulse, which fluctuates widely during periods of excitement or fatigue; attacks of palpitation of the heart; dryness of the skin, or in many cases the reverse, excessive perspiration of the hands and feet; sudden startings on going to sleep; muscular twitchings in one muscle or a group of muscles; chilliness and creeping sensations along the spine; numbness or abnormal sensations of heat in the skin of the body or limbs; itching of the skin; eruptions upon the skin, chiefly of the type of eczema; frequent gaping, yawning, or stretching; frequent seminal emissions; weakness of the bladder and rectum; and disturbances of the digestive functions.

The distinction between cerebral and spinal neurasthenia which has been shown to exist can not be made in each and every case, because various combinations of the symptoms of the two are often encountered in the same individual. A prominent author upon this type of diseases very aptly compares the nervous system of man to certain mountainous regions, since it causes so many echoes and reverberations. He says: "An irritation at one point may be transferred to any other point, following the paths of least resistance and making itself felt in those parts that are least able to resist molecular disturbances. Thus, for example, seminal emissions and spermatorrhœa, when they arise through abuse or through spinal cord disease, almost uniformly react on the brain—robbing the sufferer of courage

and manliness, exciting various phases of morbid fear, of which I shall speak, with aversion of the eyes and countenance."

I have known a decayed tooth to cause persistent earache, and in one case to cause the corresponding eyebrow to become white. In male children a tight foreskin not infrequently creates sufficient irritation of the sexual organs to induce spasms or paralysis of the lower limbs by an indirect effect upon the spinal cord. I have cured some patients, who have come to me for relief from persistent and excruciating attacks of neuralgia, by a correction of some defect in their eyes by means of glasses. The strain and irritation produced upon the brain by the involuntary efforts made by these patients to see objects with distinctness or to read and write had reacted upon the nervous system; and it would have continued so to react till death if the cause of the irritation had not been removed.

It may be well to consider a few of the more prominent manifestations of nervous exhaustion separately. Among these, sleeplessness, a defect in vision known as asthenopia, sexual weakness, headache, an unnatural dryness of the skin and mucous surfaces or profuse sweating of the hands, and morbid fears or melancholia, deserve special mention.

Insomnia.—Sleeplessness may assume different forms. Some of those afflicted have difficulty in getting asleep; some awake after a few hours of slumber and remain so until daylight; a few find themselves overpowered with a desire for sleep during their working hours, when their business will not admit of it, and at night can not obtain sleep except under narcotics. I have had patients who have told me that they spent most of their nights for years in writing to friends, riding in the horse-cars, or walking the streets for amusement because they could not sleep. It is safe to assert that persistent insomnia, extending over a period of weeks or months, indicates disease of some kind. In patients who have passed the age of fifty, or in younger persons who have indulged to excess in alcohol, it is often due to a type of kidney disease, to detect which repeated examinations of the urine are required. This form of trouble is known as the "granular" or "contracted kidney"; and insomnia, frequently combined with headache, is one of its most prominent symptoms. Obstinate sleeplessness is the cause of many a suicide, too often the starting-point of the opium and chloral habit, and surely the destroyer. I would caution you against allowing this symptom to remain uncontrolled for any length of time, and to avoid the use of all forms of narcotics as long as possible. The chains of intemperance are but silken threads when compared to those of the opium or chloral habit.

Asthenopia.—This type of defective vision can not be relieved by ordinary glasses, nor does it respond quickly to the customary suggestions of gymnastics, horseback-riding, etc. It is due to a peculiar weakness of the muscles which control the movements of the eyeballs, and it manifests itself chiefly as a sense of extreme weariness when the eyes are steadily employed for short periods of time. It is an indication of neurasthenia, and is of great diagnostic value. In severe cases it becomes necessary to divide the tendons of the stronger muscles of the eye, in order to relieve the weaker ones of a strain. It is common among near-sighted and far-sighted persons. I have seen patients who could not sew for five minutes at a time from this cause, and others who would be made sick by attending a theatre, picture gallery, or other places of amusement.

Headache.—Many attacks of this character are undoubtedly to be attributed to imprudences in eating, exposure, or fatigue. But I believe that many of those who are periodically afflicted in this way owe their suffering to a lack of tone in the muscular coat of the blood-vessels of the brain, consequent upon some of the causes of neurasthenia mentioned. I have seen a large number of instances where the *eyes were the cause of such headaches*, and where the adaptation of glasses has brought immediate relief. The medical profession are rapidly becoming enlightened upon this fruitful cause of pain. It is well also to examine the urine when persistent or periodical headache occurs, as it may be a symptom of kidney disease. Some neurologists believe that the so-called "sick headaches" are to be regarded as but a modified form of that condition which produces epilepsy. A volume might be written upon this symptom alone.

Dryness or Unnatural Moisture of the Skin.—Some nervous patients suffer from an unnatural dryness of the skin, the throat, and the nose. They are also liable to experience dyspeptic symptoms at the same time, which is probably due to similar changes in the lining of the stomach. This dryness may be accompanied also by an itching of the affected parts or an attack of eczema. A burning sensation is sometimes produced. I was once consulted by a patient who had for years been in the habit of incasing himself in flannel and putting on flannel stockings before he retired, in order to overcome a sense of burning in the skin which followed the contact of cotton or linen with any part of his body. I recall a case where the feet were once frost-bitten, and the patient has never since been able to walk upon a carpeted floor on account of a burning sensation which immediately follows. He takes off his shoes as the last step before retiring.

On the other hand, many patients afflicted with neurasthenia suffer from a profuse sweating of the palms of the hands. This is accompanied in some instances by a flushing and redness of the face, neck, and ears. The nails may become unnaturally soft or brittle.

Morbid Fears.—This peculiar manifestation of nervous exhaustion may assume one of several types. Attempts at classification of these morbid fears have been made by some authors, such as fear of lightning, of places, man and society, solitude, accident, etc., and special names have been applied by them to each of these types. Fears of this kind may be present without any other manifestation of mental impairment. They are usually uncontrollable, in spite of the fact that the patient may exhibit a knowledge that they are groundless and absurd. They seem to take full possession of a being, and to cause mental torture of an extreme kind.

Finally, melancholia is not an infrequent symptom of neurasthenia. It may be accompanied by paroxysms of laughing, weeping, and hysterical phenomena.

Now, in the treatment of neurasthenia, electricity is one

of our most effective agents. After the exciting cause has been discovered and the possibility of its continuance removed, we may safely begin the use of electricity with the brightest prospect of a radical cure. General faradization, central galvanization, and the use of franklinism are particularly of service. Of the latter I can speak in the highest terms. Neurasthenic patients often feel its beneficial effects immediately. It should be applied daily by the insulation method, the electric wind, or the static spark, as the circumstances of the case seem to indicate.

My remarks made in a previous lecture respecting massage and other adjuncts to electrical treatment are particularly applicable to this class of patients. No effort should be spared in your treatment to promote constitutional vigor by exercise, judicious feeding, good hygienic surroundings, and the like.

You, as physicians, will have to decide such matters for yourselves, and advise your patients respecting them with references to the symptoms which are to be combated. Do not trust too implicitly in electricity alone (valuable as it may be as a means of cure). Active employment will be necessary to a cure in some cases; absolute physical and mental rest will aid in others; some will require travel or a change of surroundings; the organs of the body will often demand special attention with a view of properly regulating their functions; and many other similar problems will have to be decided before a cure can be predicted by the aid of electrical agencies.

In bringing this course of lectures to a close, gentlemen, I can not but feel that much has been, of necessity, omitted by me which would be of benefit to you. A more complete course upon electro-physics, for example, would have been given had I not felt that text-books on physics would furnish you with the requisite knowledge when needed, and that the time allotted by me to the consideration of electricity could be better spent in dealing with the practical applications of this agent in the diagnosis and treatment of disease. In these respects even this course is far from complete. It is but a hasty sketch of the more important facts.

It is well for each of you to bear constantly in mind that electricity as a therapeutical agent is yet in its infancy. Facts are being daily brought to light, however, which will aid us in employing it upon the sick to better advantage, and in obtaining more uniform results. As fast as new discoveries are published they will naturally be subjected to tests by those laboring in this field, and, if their value is proved, they will in time become generally recognized and employed by the profession.

Perhaps some of this class of students may be among the number who are destined to promote the growth of this department of therapeutics by their inventive faculty, original research, or clinical observation. I trust that it may prove so.

If I have succeeded in awakening your interest sufficiently to induce any of you to pursue this line of study further with intelligence, and thus to give possible benefit to others, I shall feel amply repaid for the many hours of thought and manual labor that I have personally spent in trying to modify and improve existing electrical appliances.

Original Communications.

THE EARLY STAGES OF HUMAN DEVELOPMENT.

By CHARLES SEDGWICK MINOT, M. D.,
BOSTON.

Part II.—Embryos of the Third Week.

In the previous article ("N. Y. Med. Journal," Aug. 22, 1885, p. 197) it was shown that in the earliest known stages of man the ovum is normally, probably, a vesicle of some 3 to 4 mm. diameter, bearing short, simple chorionic villi, and having at one side in its interior a small heap of rounded cells, which mark out the so-called germinal area. In other placental mammals a corresponding stage occurs, and is followed in them by a stage characterized by the appearance of the so-called primitive streak and groove—temporary structures, which show, however, the axial line of the future embryo. This stage is again followed by a third, in which the medullary folds and groove arise; the former are two longitudinal ridges on the outer surface of the germinal area. These ridges begin in front of the primitive streak, and run back alongside it; in front the two ridges unite; the depressed space included between them is the medullary groove. The fourth stage (His's fourth and fifth) is characterized by the appearance of the first myotomes (protovertebræ) and the commencement of the closure of the medullary groove to form the medullary canal. The closure is effected by the groove growing deeper and narrower until the upper edges of the lateral ridges come in contact and finally coalesce.

We distinguish these four stages:

First. Stage of the germinative area.

Second. Stage of the primitive streak.

Third. Stage of the medullary groove.

Fourth. Stage of the myotomes.

The known specimens of the first stage have been already considered. No human ova of the second stage have yet been described. His suggests that Schwabe's embryo (7) and Bruch's (10) may have been in the third stage. Schwabe's embryo I consider much older, and have referred to it, accordingly, below. In regard to Bruch's ovum I will not venture an opinion, as his description is not a very available one. Of the fourth stage we have four specimens recorded, but, unfortunately, not one of them has been described adequately, according to the present standards. We proceed to their consideration.

3. The youngest known human embryos (fourth stage).

As just stated, the number of these is four. Their probable age is about fourteen days. The least advanced is His's embryo E (1, Heft i, p. 145), of which only His's sketches are available, the attempt to microtome the specimen not having been fortunate. The ovum was presumably normal; it measured 8·5 by 5·5 mm., and was entirely covered by short branching villi. For the convenience of the reader I have constructed from the author's sketches and descriptions the accompanying diagram. His states that

the chorionic vesicle bore at one point a thick stalk, *Al*, which ran to the posterior end of the embryo; the length

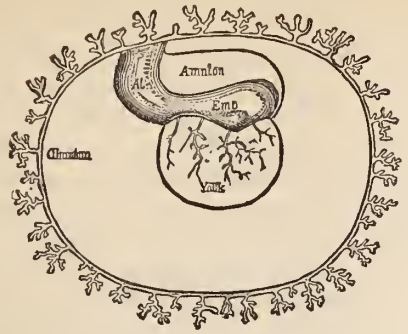

Fig. 1.—Diagram of His's Embryo E. Age 14 ? days; length about 2·3 mm. The embryo is not represented in quite its natural attitude; the proportion of the parts is not accurate; the villi of the chorion and the vessels on the yolk are purely diagrammatic as to their number and shape. *Emb*, embryo; *Al*, supposed stalk of the allantois.

of the embryo from the anterior extremity to the base of the stalk was 2·6 mm. The head end of the embryo was somewhat thickened, and apparently showed the medullary groove still open; that is, the tube of the central nervous system was not yet closed. The small, round yolk-sac had a broad connection with the ventral surface of the embryo. The amnion sprang from the allantois and passed over the head of the embryo. The disposition of the caudal extremity was not made out. There were no limbs, gill-clefts, nor organs of any kind discernible—not even a protuberance between the head and yolk-sac, such as marks the position of the heart in older embryos.

Allen Thomson (2) published an excellent article on young human ova in 1839. He gives a very good critical review of what previous authors had written, and describes himself three embryos, which have become classical, for the figures and descriptions given of them by Thomson have been copied again and again. They are especially known by the reproductions in Kölliker's embryologies and in Quain's Anatomy. Two of these embryos (numbered i and ii by Thomson) belong in the group we are now considering. I can not, however, admit at present that either of them is certainly fully normal, though, perhaps, they are only slightly malformed.

In number i (see Kölliker's "Grundriss," 1884, Fig. 112, and "Entwickelungsgeschichte," 1879, Fig. 225) the yolk-sac was abnormally dilated and the characteristics of the embryo were not ascertained. His (1, Heft ii, 35, 36) has shown that probably the embryo proper was not observed, and that what Thomson called the embryo was really only the amnion, springing from the allantois-stalk and passing over the embryo. Kölliker questions the accuracy of this interpretation, but upon what ground is not evident, for, so far as I can see, it accords perfectly with our present knowledge. The embryo in question was presumably little advanced beyond His's embryo E, Fig. 1, but had an abnormally hypertrophied yolk-sac. As no sufficient description of the embryo exists, and as it is quite certain that the specimen was more or less abnormal, it can not be longer regarded as a fair representative of a young ovum.

Much more valuable is the account of Thomson's second ovum, which he had better opportunities of studying. The original description has been supplemented by His (1, Heft ii, 34, 35), who has examined Thomson's original drawings and called attention to an important error in the engraving in Thomson's plate. Kölliker, however, still reproduces the incorrect figure in the second edition of his "Grundriss," Fig. 114. An erroneous figure is also reproduced in Ecker's "Icones," Taf. xxv, Fig. 3. The chorionic vesicle measured 0·60 by 0·45 of an inch, and was covered with branching villi. The contained embryo was very small; according to Kölliker, only 2·5 mm. The embryo rested upon the round yolk-sac of 2·2 mm. The embryo consisted of two thick longitudinal ridges (Fig. 2, A), which curved round in front so as to become continuous with one another, and *were broken off posteriorly*—an important fact noted by His (*cf. sup.*). These ridges are presumably the medullary

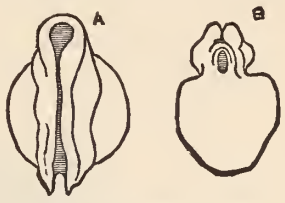

Fig. 2.—Thomson's Second Ovum. A, embryo from above; B, embryo from behind.

folds. At the hind end of the embryo was a tear, making a hole into the hollow yolk-sac. As His suggests, this is probably where the allantois was inserted and broken off. No amnion was observed, and the nature of the connection of the embryo with the chorion was not ascertained. What we learn from this embryo is something more definite than is afforded by His's observations as to the size and disposition of the medullary ridges and the hollowness of the yolk-sac. The evident hypertrophy of the yolk-sac enforces caution as to accepting the embryo as normal; but it is not rare to find in abortions a small typical embryo with an enormously dilated chorion, so that it is not impossible that the embryo in the present case was quite normal.

The fourth embryo of this group, His's SR (1, Heft i, 140–144), measured 2·2 mm. in length, and was probably fourteen days old. The chorion was 9 by 8 mm. in diameter. It shows considerable advance of development beyond the three embryos above considered. The neck of the yolk-sac is already somewhat contracted, or, in other words, the connection between the embryo and the yolk-sac is no longer so broad and long as it was. The head is considerably enlarged; between it and the anterior wall of the yolk-sac is a large thickening corresponding to the heart. From the under side of the caudal extremity runs off the stalk of the allantois, which is still short and thick; the amnion lies quite close to the embryo; the medullary ridges are still separated by an open, though deep, and relatively narrow groove; myotomes (protovertebræ, *auct.**) are present, but their

* It must be remembered that the term protovertebræ is an entire misnomer, and is inherited from the time when the primitive muscular segments (myotomes) were mistaken for the commencements of the vertebræ. Kölliker has maintained that they participate in the forma-

number was not ascertained. When the embryo is viewed in profile, the middle of the back shows a marked concavity, which has been noticed in other older embryos, and is, probably, an artificial distortion. We shall have to return to this matter. Small openings were visible on the inner surface of the chorion. These I take to be the openings to the still hollow villi, such as have been seen in both younger and older ova. His attempted to obtain sections of his specimen, but, when cut, the sections fell into fragments.

Summary.—The development of the chorion and amnion in man is exceedingly precocious. The youngest embryos known are in the neighborhood of 2·2 mm. in length. (Thomson gives the length of his embryo i as 2·5 mm., but the criticisms made above render it plain that this measure probably refers to the length of the amnion plus the allantois-stalk; the embryo not seen by Thomson was presumably shorter.) The embryo has a broad attachment to the yolk-sac, which in diameter nearly equals the length of the embryo and is already furnished with blood-vessels. The most conspicuous character of the embryo is the presence of two very thick dorsal ridges—medullary folds—running the whole length of the embryo and inclosing the medullary groove—central nervous system to be—between them; the cephalic extremity is somewhat thickened; from the ventral side of the caudal extremity springs the short and thick allantois-stalk, the opposite end of which is inserted into the chorion. The amnion completely incloses the embryo and is attached on the one hand to the allantois-stalk, on the other to the embryo nearly parallel to the junction of the embryo and the yolk-sac.

The next change involves not merely the growth of the embryo, but also the thickening of its cephalic end, the development of the great heart protuberance between the yolk-sack and the head, the concave flexion of the back, and the deepening of the medullary groove, which, however, still remains open.

The chorion forms a relatively large vesicle, its average diameter being about 8 mm., but the four specimens vary from 5·7 to 15 mm. The chorion bears villi over its whole surface; the villi are considerably branched. Probably the villi are formed chiefly if not solely by epithelium, and probably also there is a layer of connective tissue, very likely already vascular, which lines the chorion but does not extend into the villi.

There are many still unsolved problems as to the early development of man. It will be observed that not a single one of the ova hitherto noticed has been adequately investigated, and that no specimens have yet been studied at all showing the first appearance of the embryo, the origin of the amnion, or of the allantois, or of the yolk-sac; and, finally, that of all the earliest stages our knowledge is extremely imperfect. It is therefore much to be hoped that all who obtain available specimens will carefully preserve them and intrust them to a competent investigator. From the above considerations it is also evident that the summary just given can be only tentative.

tion of the vertebræ, but even this view is entirely erroneous. The term protovertebræ ought to be immediately banished for ever.

4. ORIGIN OF THE ALLANTOIS.

It will be remembered that in birds the allantois very early becomes a free sac. It has been supposed by some writers that the allantois of man grew out in the same manner. Haeckel even went so far as to prophesy that when a human embryo of the right stage should be obtained it would be found to have a free allantois. Very shortly after W. Krause (3) published a description of an embryo with free allantois which he stated was human. Both Haeckel and Krause were, however, mistaken, the former through hasty and unfounded speculation, the latter from an error as to the identity of his embryo. Krause's embryo was, I think it may be said certainly, not human, probably not even mammalian, but avian. Krause still maintains that it is human; it agrees in all essential particulars with a chick, and disagrees utterly in shape with all known normal human embryos. The discussion as to this specimen was long and animated, but has now little interest except historically. In the literature cited at the close of this article I have given the reference to Krause's original article, and under the same head (3) references to the discussion.

To explain the origin of the human allantois we have only the following hypothesis of His, no direct observations being available. In an earlier stage the embryo is supposed to form over the germinal area upon the surface of the blastodermic or chorionic vesicle; below it lies the yolk-sac (see the accompanying diagram, Fig. 3, A, *V*); on all sides

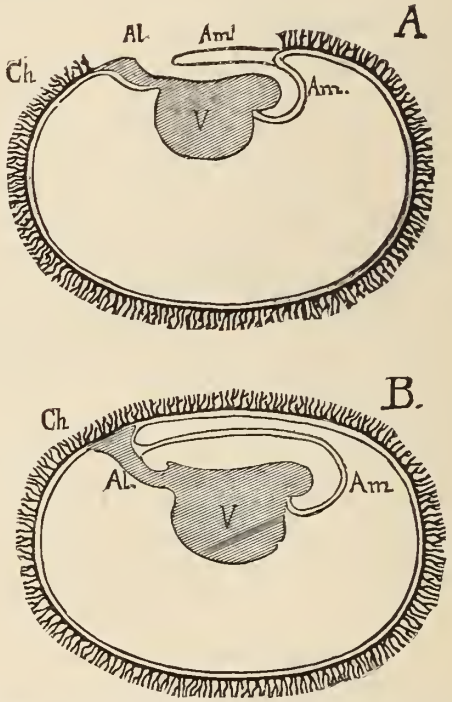

Fig. 3.—Diagrams to show the Formation of the Human Amnion. A, first stage; B, second stage; *Am*, amnion; *Al*, allantois; *Ch*, chorion, the villi of which are drawn smaller and more numerous than they are in nature; *V*, yolk-sac.

the tissue of the embryo passes over into the chorion, *Ch*; posteriorly the connection between the embryo and the chorion is marked by a thickened band (probably of mesodermic cells originally part of the hind end of the primitive streak); this thickened band persists and becomes the allan-

tois-stalk; around the head of the embryo a fold is formed, *Am*, the beginning of the amnion; this fold grows back farther and farther over the embryo as indicated by the dotted line, *Am'*, Fig. 3, A; finally the tip of the fold reaches the allantois-stalk, and, uniting with it, produces the arrangement shown in Fig. 3, B, which is the same as Fig. 1, and is known from actual observation.

This account may be accepted as hypothetically correct. I think it probable that the allantois first arises as a heap or mound of cells, pre-anal and ventral in position, and having a very small, short, nearly cylindrical cavity, which in its turn arises as a diverticulum of the hind gut, and is, therefore, lined with entoderm. This is the manner in which the allantois starts apparently in all amniota in regard to which observations on this point are available; general analogy leads us to expect that in man also the course of development is similar. But since in man there is no caudal amnion, nothing intervenes, so far as we know at present, between the allantoic outgrowth of the embryo and the chorion; hence it seems the primitive connection is maintained, and there is never a free allantois save that it forms at first for a short time a small more or less independent protuberance.

A word as to the homologies of the allantois. Its proximal portion becomes, as is well known, the bladder of the adult. It has been maintained by Balfour ("Comparative Embryology," ii, p. 256), and it is the generally accepted opinion, that the allantois is evolved as a modification of the bladder. This view I believe to be erroneous; the bladder of amphibia is a *dorsal* diverticulum of the intestine, and can not be homologized with the amniote bladder, which is a *ventral* diverticulum. The amphibia (and ganoids) have, too, a long-known embryonic structure, which is a ventral diverticulum of the intestine and extends into a considerable accumulation of mesodermic cells below the blastopore (anus). This diverticulum I hold to be a rudimentary allantois, and, in fact, it precisely agrees, even as to details, with the commencing allantois of amniote vertebrates. This obliges us to consider the allantois as primitive, and the bladder of the *Amniota* as a secondary deriva-

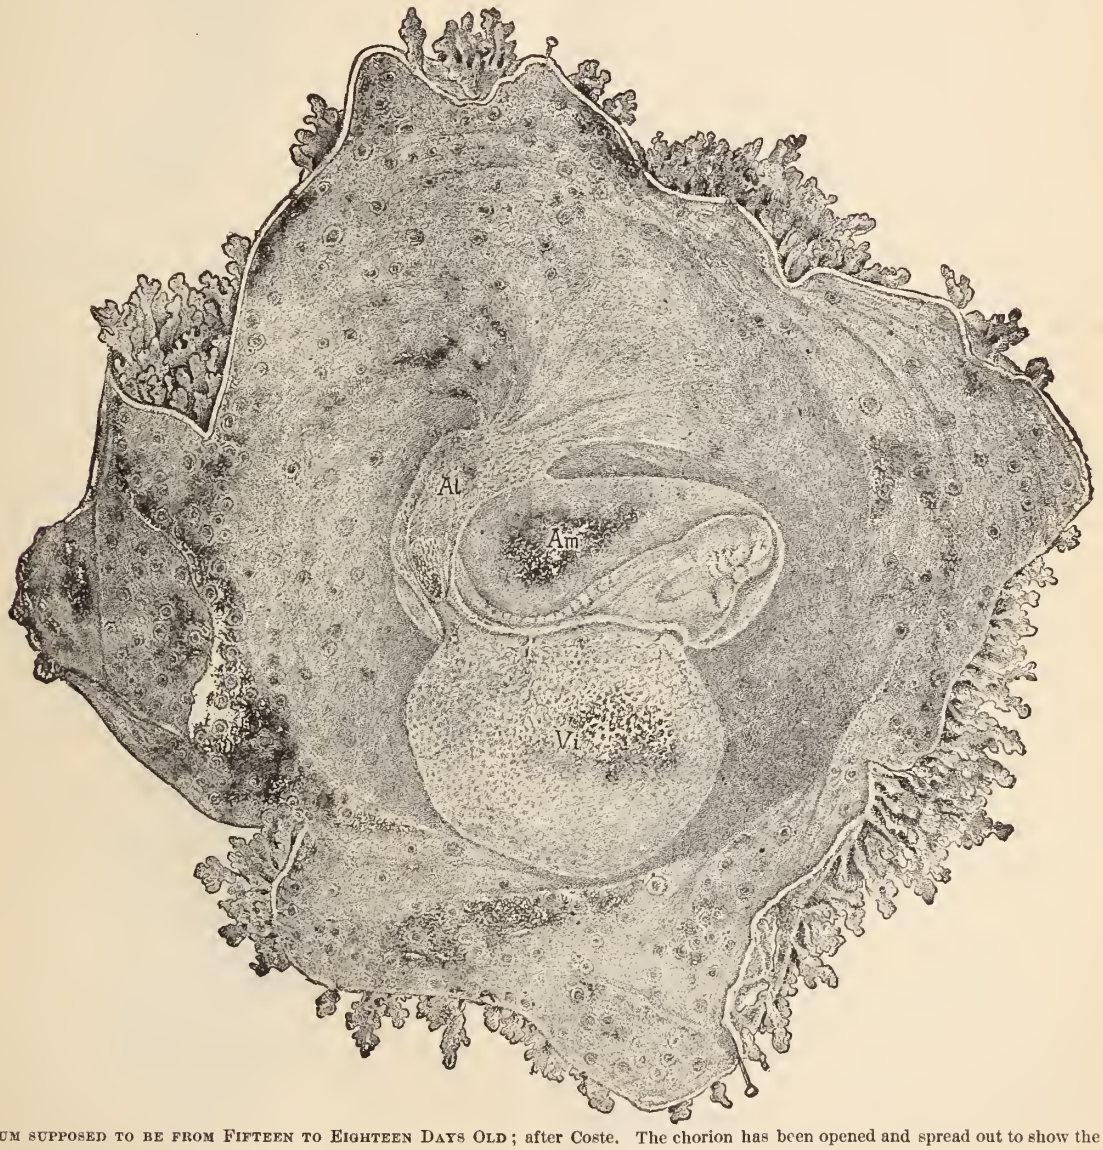

FIG. 4.—OVUM SUPPOSED TO BE FROM FIFTEEN TO EIGHTEEN DAYS OLD; after Coste. The chorion has been opened and spread out to show the embryo and its annexa. *Al*, allantois-stalk; *Am*, amnion surrounding the embryo.

tive of the allantois, precisely the reverse of Balfour's theory. The homology drawn also renders it probable that the allantois arose very early, since we find traces of it in the ganoid fishes. In this case it will no longer be strictly accurate to regard *Allantoidea* and *Amniota* as synonymous terms, as they are now used. On the contrary, it appears that the *allantois is a much older structure than the amnion, and the bladder of the Amniota is a modified allantois and not homologous with the bladder of the Ichthyopsida.*

5. EMBRYOS OF THE FIFTH STAGE.

Formation of the Gill-Clefts.—We now reach a series of embryos, several of which have been well studied and beautifully drawn. Two of them belong to the stage now under consideration—namely, the youngest embryo described by Coste in his great work, and His's embryo L. Both descriptions are satisfactory, save that in regard to the dimensions of Coste's embryo no certainty can be had. Coste's private collection is, I believe, now in the College of France, but upon search this particular specimen could not be found, so that His's inquiries to ascertain its actual length were resultless. Kölliker states that it was 4·4 mm. long, but his authority for the statement is not given; the measure was probably taken from Coste's figure marked "*grandeur naturelle.*" Since embryos of this length are far more developed than Coste's, it is probable that Coste's data as to the magnification of his figures are inaccurate. If we assume the embryo to have been really about 2·5 mm. long, it will then agree, except as to the great length of the rump, very closely with what we know otherwise of such young embryos.

I give the accompanying figures, which are careful copies from the original plates published by Coste (4, Espèce humaine, Pl. II), whose illustrations, made by his assistant, Gerbe, have never been surpassed for beauty and life-like accuracy. The embryo in question was inclosed in a villous chorion, Fig. 4, and was provided with a large vitelline sac, *Vi*, having a very broad connection with the embryo and covered with a network of vessels, in which was a fluid not yet red. A thick allantois-stalk, *Al*, can be seen running from the under side of the embryo's tail to the chorion; from the anterior side of the stalk springs the amnion, *Am*, completely inclosing the embryo. It is important to notice that in this, as in still older embryos, the disposition of the amnion is essentially the same as in the earliest stages (*v. sup.*); the line of attachment of the amnion is down the sides of the allantois and around the embryo about on a line with the top of the yolk. As regards the embryo, it is drawn slightly canted on to its left side; its back is concave; the head end is thickest, and shows three gill-arches, hence there were probably two branchial clefts; behind and below the gill-clefts can be seen the heart, already a bent tube, shining through; behind the arches again, but on the dorsal side, the light-looking œsophagus is distinguishable; in the figure a wedge-shaped shadow intervenes between the straight œsophagus and the bent heart; the heart causes a conspicuous bulging of the body between the head and the yolk-sac; the caudal extremity is thick and rounded, and curves upward.

Fig. 5 is a ventral view of the same embryo after most of the yolk-sac has been cut off; its walls, *Spl* (splanchnopleure), are seen to pass over without any break into those of the intestinal cavity. In the central line the chorda

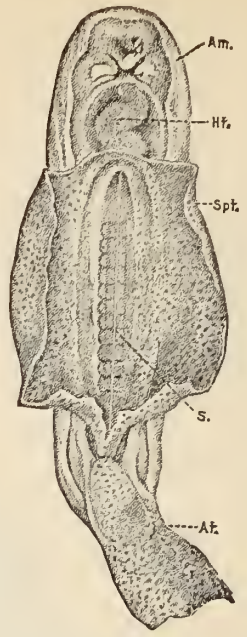

Fig. 5.—Embryo supposed to be from Fifteen to Eighteen Days Old; after Coste. Ventral view; the vitelline sac has been removed. *Am*, amnion; *Ht*, heart; *Spl*, splanchnopleure, extending beyond the embryo to form the yolk-sac; *S*, chorda dorsalis with a row of myotomes on each side; *Al*, stalk of the allantois.

dorsalis, *s*, can be perceived through the translucent dorsal wall of the intestinal cavity; it is flanked on each side by the row of square muscular segments (myotomes). We see the large allantois, *Al*, behind, and in front the tubular heart, *Ht*, with a decided flexure to the right of the embryo; the anterior end of the heart makes an opposite bend, separating off a limb, which becomes the *bulbus aortæ.*

The chorion consisted of two membranes, one of which passes continuously over the inner surface of the chorion, while the other outer membrane alone forms the hollow villi, Figs. 4 and 6; hence, in looking at the inside of the

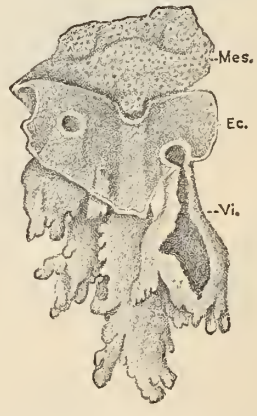

Fig. 6.—Fragment of the Chorion of Fig. 4, highly magnified. *Ec*, epithelial layer; *Mes*, connective-tissue layer; *Vi*, chorionic villi, formed wholly of epithelium.

chorion, we see numerous round openings which do not penetrate the inner membrane. Fortunately we learn from

Kölliker ("Entwickelungsgeschichte," 1879, p. 309), who had an opportunity in 1861 to examine this chorion, that the outer membrane was epithelial, with cells of the same character as in the epithelium of older vascularized villi,* and that the inner layer consisted of developing connective tissue and carried fine blood-vessels. It thus appears that Coste was the first to observe the rôle of the epithelium in the growth of the villi, which was discussed in the previous article.

(To be concluded.)

HYDRONAPHTHOL;
A NEW ANTISEPTIC.

By GEORGE R. FOWLER, M. D.,
SURGEON TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

(Continued from page 375.)

In order to satisfy myself as to the solubility of this compound, observations having in view the determining of this point with some degree of accuracy gave the following: In hot water it will dissolve in the proportion of one part in a hundred, and a residue of an oily or tarry substance occurs, which latter, upon boiling the solution, melts and floats about on the surface. If the water be only warmed to a temperature of 70° C., the residue is found at the bottom of the flask. Upon filtering the solution and allowing the filtrate to cool to 17° C., the excess of hydronaphthol crystallizes, leaving a solution of the strength of 1 to 800. By reducing the temperature still lower, or by vigorous shaking, a further quantity is thrown down, leaving a solution of the strength of 1 to 1,100, which latter remains permanent.

It dissolves in cold water to the extent of one part of the hydronaphthol to two thousand parts of water. To effect this, however, it is necessary that it should remain in contact with the water, or be occasionally agitated. The clear filtrate from this solution has the characteristic taste of hydronaphthol and possesses antiseptic properties.

To test for the presence of the hydronaphthol in solution, add a few drops of the solution of the subacetate of lead, when a white precipitate will be thrown down. Or the addition of chloride of sodium to the solution will cause its separation in a fine white precipitate, giving the liquid a milky appearance.

The tarry material which floats about in a melted condition upon the surface of the hot solution is probably alpha-naphthol, an impurity which will, no doubt, be gotten rid of in the course of a further experience in the manufacture of the compound. It does not interfere with the antiseptic qualities of the solution, nor does it do other harm, as far as is at present ascertained.

In order to ascertain to what extent hydronaphthol could be relied upon to prevent the occurrence of putrefactive changes in animal tissues and fluids, the following preliminary observations were made:

First, three solutions were prepared for use, the first containing 1 gramme of hydronaphthal in 1,000 grammes of warm water, the second containing 1 gramme in 1,500 grammes of water, and in the third 1 gramme in 2,000 grammes of water. In all of these solutions fresh animal tissue (beef) was placed, and, to afford a control test, a piece of the same beef was placed in a similar flask containing pure water, and all of the tests were exposed to a temperature of about 21° C. in an ordinary room, and as nearly as possible to the same general conditions, with the following results: At the end of twenty-four hours the flask containing the beef and water only showed signs of decomposition, and in the course of another twenty-four hours had broken down completely. The other three flasks, after one hundred and twenty hours' exposure, were found to have undergone no change, and were in a perfect state of preservation.

As beef solution is the medium generally employed for the purpose of testing the power of antiseptic substances, the following experiments were made: The beef solution was first filtered while hot, and then solutions of hydronaphthol made in this vehicle. In the first 1 gramme of hydronaphthol was dissolved in 1,000 grammes of the warm beef solution, in the second 1 gramme was dissolved in 1,500 grammes, and in the third 1 gramme was dissolved in 2,000 grammes. A control test was likewise prepared in the same manner, but without the addition of the antiseptic. These were all placed under the same conditions, as to temperature, etc., as in the preceding experiments, with the following results: At the end of twenty-four hours the control test began to exhibit some turbidity, and before forty-eight hours had elapsed indubitable signs of advanced decomposition were present. All three of the solutions containing the hydronaphthol, however, at the end of one hundred and twenty hours, were found in their normal condition.

The addition of 1 part of the antiseptic to 1,000 parts of fresh urine has maintained the latter in a perfect state of preservation for four months, and probably will continue to do so indefinitely. Solutions of glue and gelatin, so prone to decomposition, have been preserved by the addition of the antiseptic in the proportion of one twentieth of one per cent. throughout the warm summer months, and in the same proportions the formation of mold or mildew was prevented in such moist organic compounds as mucilage, starch and glue pastes, dyewood and other extracts.

The results of these observations encouraged me to seek still further light upon the subject of the antiseptic properties of hydronaphthol, and to ascertain to what extent its preservative powers could be carried, and to likewise determine if these depended upon a germicidal action on the one hand, or upon a simple inhibition of the growth of bacteria on the other. With this end in view, I sought the assistance of Dr. G. M. Sternberg, the well-known authority upon disinfectants and antiseptics. That gentleman was about to sail for Europe to be gone for a period of six months or longer, but proffered me the services of his first assistant, Dr. Abbott, at the laboratory of the Johns Hopkins University, in Baltimore. These I gladly accepted at once, and during the past three weeks experiments having the

* "Hierbei zeigte sich, dass die Zotten und die sie tragende Haut ganz und gar aus epithelartigen Zellen, von derselben Beschaffenheit, wie die des Epithels der späteren gefässhaltigen Chorionzotten bestehen."—Kölliker, *l. c.*

object of determining the following points have been carried on: First, its germicide value on broken-down beef-stock containing pathogenic spore-bearing organisms, micrococci, and putrefactive bacteria; second, its value in destroying pure cultures of anthrax and pure cultures of pathogenic micrococci; and, third, its value as an antiseptic (the prevention of development without killing the organisms).

In the first place, the insolubility of the hydronaphthol was found to be an insuperable bar to any germicidal action in its normal solution (0·1 per cent.). A mixture was therefore made of 1 gramme to 100 c. c. of water (1·0 per cent.), this being about ten times above saturation. This mixture was tried on putrefied beef-tea containing putrefactive and pathogenic organisms and spores, on anthrax pure, on subtilis pure, and on pure cultures of pathogenic micrococci. To these it was added in equal proportions—that is to say, ten cubic centimetres of the substance to be disinfected and the same quantity of the one-per-cent. mixture of hydronaphthol were added together. This gave five tenths of one per cent. (0·5 per cent.) of the hydronaphthol present, being five times above saturation. A drop of the fluid containing the organism was, after two hours' exposure, introduced into the flasks containing sterilized solution of beef peptones, the culture medium generally used in disinfectant experiments, and, after the standard length of time of exposure in the incubator (two hours), in all the tubes the respective organisms were found to be present. This showed that when the substance was present in a mixture five times above saturation it was not germicidal to these organisms and spores. These experiments seemed to at once settle the question as to its germicidal powers.

In order to test its power as an antiseptic, the following experiments were made: Eleven flasks were prepared, each containing 100 c. c. of solution of beef peptone, to which hydronaphthol was added in the following proportions: 1 to 100, 1 to 500, 1 to 800, 1 to 1,000, 1 to 2,000, 1 to 4,000, 1 to 6,000, 1 to 8,000, 1 to 10,000, 1 to 16,000, and a flask in which none of the antiseptic was placed. These were inoculated with two drops of decomposed beef-tea, and placed in the incubator. The flask put up for comparison, and which contained none of the hydronaphthol, broke down completely in twenty-four hours. The other flasks, from the strongest up to the 1-to-6,000 solution, and including the latter, after one hundred and twenty hours' exposure in the incubator, resisted the development of decomposition, the first failure taking place in the 1-to-8,000 flask.

The following is a summary of these experiments:

1. As a germicide it failed to disinfect decomposed beef-tea containing pathogenic organisms and spores when present in 0·5 per cent. 2. It failed to prove germicidal to pure anthrax, pure subtilis, and pure micrococci, in the same strength. 3. As an antiseptic it proved to be active in arresting the development of the bacteria in the proportion of 1 to 6,000, and failed only when the 1-to-8,000 solution was reached.

That the value of an antiseptic agent does not necessarily depend upon its germicidal powers is a well-established fact;* it is further well known that some agents of well known germicidal power are inapplicable as antiseptics. To the class of agents which prevent or arrest putrefactive changes, without necessarily destroying the organism upon which these changes depend, but rather whose potency is attributable to their influence in holding in check their development, Lister has given the name of "inhibitory" agents, or antiseptics having an "inhibitory action."†

The importance of this distinction can not be overrated, for it has been the custom in the past to use the words "germicidal," "disinfectant," and "antiseptic" in a loose manner, and, in some instances, as synonymous terms. The impropriety of this is at once obvious, and it is now growing to be the custom to speak of such substances as are both germicidal and antiseptic as simply germicides or disinfectants; while those which are antiseptic without possessing the power of killing organisms endowed with a peculiarly tenacious hold upon life, such as those of anthrax and pathogenic micrococci, are called simply antiseptics. For the present, this distinction will perhaps be the best attainable, with our present want of knowledge of the life-history of these lower organisms. For instance, Sternberg‡ asserts, and there can be no reason for questioning the opinion of this authority, that "the vital resistance of bacterial organisms to chemical reagents differs, within certain limits, for different species." Hence, unless some standard of vitality, so to speak, were established, different observers would use the distinctive terms "disinfectant," "germicidal," and "antiseptic" with different meanings, and no end of confusion would result. It is perhaps best, therefore, that the term germicide or disinfectant should be limited to such agents as will destroy reproductive spores, inasmuch as these possess powers of resistance far in excess of bacterial organisms in which active development takes place by the process known as "multiplication by fission."

Taking, therefore, the reproductive spores, such as those of the anthrax bacilli, as the standard for the test of strength of a germicide, very few of the agents supposed to be active germicides are found to be efficient in solutions which would be safe to employ in practical surgical work. The most notable exception to this will be found in corrosive sublimate, and, as elsewhere shown, this agent is not a stable antiseptic. But, when the next most popular antiseptic, carbolic acid, is brought forward for comparison, its impracticability for general use as a germicide will be at once apparent when the statement is made, upon the authority of Koch,# that, for the certain destruction of the spores of the anthrax bacilli, an aqueous solution of carbolic acid of the strength of 1 to 10 is necessary. This, for purposes of application in wound treatment, is manifestly impracticable.

The well recognized rule‖—that "*The effect which a substance introduced into a wound as an antiseptic may have on the exposed surfaces of the wound must be taken into consid-*

* Koch, "Mittheilungen des Kaiserlichen Gesundheitsamtes," Band i, Berlin, 1881.

† "British Medical Journal," October 25, 1884, p. 804.

‡ "American Journal of the Medical Sciences," April, 1883, p. 343.

"Mittheilungen des Kaiserlichen Gesundheitsamtes," etc., p. 236.

‖ Pilcher, "The Treatment of Wounds," New York, 1883.

eration in choosing one for use, as well as its effect upon the germ supposed to be present"—has a direct bearing upon the question at issue.

Of all the substances which are at present known to have an inhibitory action upon bacteria, and hence are in the true sense antiseptic, with the sole exception of corrosive sublimate, hydronaphthol is the most powerful. By reference to the following table, adapted from Sternberg by Pilcher,* showing the comparative value of the agents named in their power to arrest the development of the micrococcus from pus, this claim will find undeniable corroboration. According to Sternberg, the other organisms of this class, bacteria termo, etc., are inhibited by about the same strength of antiseptic as that necessary for pus micrococci, and therefore this table may be cited for purposes of comparison:

TABLE OF MINIMUM STRENGTHS OF ANTISEPTIC AGENTS REQUIRED TO INHIBIT GERM-DEVELOPMENT.

Antiseptic agent.	Efficient in the proportion of one part to
Mercuric bichloride	35,000
Iodine	4,000
Sulphuric acid	1,800
Carbolic acid	500
Salicylic acid and sodium biborate, equal parts	200
Boric acid	200
Ferric sulphate	200
Sodium biborate	100
Alcohol	10

According to the experiments above detailed, hydronaphthol is efficient in the proportion of between 1 to 6,000 and 1 to 8,000, and in the table just quoted would occupy the position next to mercuric bichloride. In other words, as an antiseptic it is about one fifth as powerful as the mercuric bichloride; from one and a half times to double the strength of iodine; four times as strong as sulphuric acid; *at least twelve times as efficient as carbolic acid; thirty times as potent as salicylic acid*, when sodium biborate is added to the latter (for the purpose of increasing its solubility) in the proportion of equal parts of each; *thirty times as powerful as both boric acid and ferric sulphate;* sixty times as strong as sodium biborate, and *six hundred times as strong as alcohol.*

In making solutions for surgical use, it is my custom to add a sufficient quantity to a teacupful of hot water to supersaturate the same; this produces a milky mixture. Sufficient water at the ordinary temperature is then added to this to make it a clear solution. Or powders of seven grains and a half each, or compressed tablets containing the same quantity, may be at once dissolved in a pint of warm water. The latter would constitute a convenient and portable form for use in private practice. In my hospital service, the irrigator jars are kept about two thirds full of the solution, having an excess of the hydronaphthol at the bottom. By adding a quantity of hot water to the solution just before it is required for use, a super-saturated solution is at once obtained. After the solution has been for a few days in contact with the excess at the bottom of the jar, the latter precaution may be found to be unnecessary. The saturated solution may be used for washing the site of operation, the surgeon's hands and those of his assistants after scrubbing with mercuric bichloride solution in case of suspected infection; for saturating towels for the purpose of isolating the field of operation; as a bath for the instruments; for washing the sponges and for irrigating the wound.

In the preparation of silk and catgut it would be safest, especially in the case of the latter, to first immerse the gut, wound upon glass or hard-rubber spools, in Kümmel's solution of mercuric bichloride (one half of one per cent.) for twelve hours, and then preserve it permanently in a one-per-cent. alcoholic solution of hydronaphthol. Silk may be boiled in the first-named watery solution of sublimate and kept, for protection, in the hydronaphthol alcoholic solution as used for the gut. This method of sterilizing catgut and silk I prefer to all others as being the safest. It has been asserted by its originator that it will afford perfect protection against infection, even though the gut be made from an animal dead of anthrax. I am particular in making this statement here in order to qualify a remark concerning the sterilizing of gut by means of hydronaphthol, made in the first portion of this article. I also prefer to trust to the well-known germicidal power of a freshly prepared solution of sublimate in the first preparation of sponges, as well as their subsequent purification after an operation, where they are used more than once. But they can be kept with advantage in the hydronaphthol solution, after sterilizing, until needed for use. So also with horsehair for sutures and drains, and rubber drainage-tubes; after sterilizing in mercuric-bichloride solution, the hydronaphthol solution, from its reliability and absence of tendency to decompose, will be found far preferable for purposes of permanent preservation. I am led to emphasize this statement by the fact that it has happened to me recently to find sponges, placed in a 1-to-1,000 solution of corrosive sublimate—which latter at first was certainly germicidal—after a few weeks developing a most sickening, putrid odor, and to afford other evidences of having undergone putrefactive changes, even showing a well-marked growth of mold upon the surface of the solution in the screw-capped fruit-jar in which they had been placed. This can only be attributed to the want of stability of the bichloride solution and the decomposition of the sublimate in the solution into the submuriate, a very feeble as well as insoluble disinfectant. This can not happen in the hydronaphthol solution, as the latter remains without change for an indefinite time (so far as can at present be ascertained), as well as preserves, against putrefactive changes, organic substances of whatever nature, particularly if these have been previously subjected to the germicidal action or sterilization of such a potent agent as a freshly prepared solution of corrosive sublimate.

When a spray is used, a solution of the strength of one per cent. in alcohol may be used in the reservoir of the atomizer. This, when mingled with the steam from the boiler of the instrument, can be diffused in the atmosphere with advantage where it is considered that a spray adds to the thoroughness of the antiseptic measures.

The softness of the crystals of hydronaphthol and the

* Pilcher, "The Treatment of Wounds," New York, 1883.

facility with which they cling to the meshes of gauze, cotton, jute, etc., render the substance peculiarly well adapted for incorporation in these materials for the purpose of rendering them permanently antiseptic for surgical purposes. Messrs. Seabury & Johnson, of New York, have made, at my request, gauze and cotton dressing containing twenty per cent. of the antiseptic, and I can testify to their efficiency and reliability.

Cushion dressings of wood-flour, paper-wool, and sawdust are used in my hospital service almost exclusively; these can be readily saturated with a warm solution of hydronaphthol in water of the strength of 1 to 500, in which also mercuric bichloride is dissolved in the same proportion. The bichloride in this solution will be sufficiently germicidal to destroy any possible source of infection, and the hydronaphthol will furnish the permanent antiseptic. No chloride of sodium need be added to the solution for the purpose of preventing the decomposition of the corrosive sublimate, as the latter will be sufficiently stable to perform its office of sterilizing the dressing, and, when this is accomplished, it is of no further use, and, in fact, will soon be converted into calomel.

After saturating the wood-flour, sawdust, or paper-wool with the above-named solution, the two former should be spread out to dry in a place free from dust. If an alcoholic or benzole solution be used, drying will go on rapidly and but slight risk be encountered of the materials becoming again infected by any possible floating germs in the air. In the case of paper-wool, the drying may be facilitated by running the material through a clothes-wringer. Should the sawdust or wood-flour dry in lumps, as it is apt to do when the watery solution is used for impregnating, these may be readily broken up by rubbing them through a common flour-sieve. When an alcoholic or benzole solution is used for the purpose, no such after-treatment of the wood-flour or sawdust is necessary.*

It is sometimes thought to be good practice to dust along the line of incision some absorbent powder possessing antiseptic properties. For this purpose I have found carbonate of magnesia, having triturated with it the hydronaphthol in the proportion of 2 to 100, a very desirable and efficient substitute for iodoform.

(*To be continued.*)

TWO CASES OF NEGLECTED EAR DISEASE IN INFANTS, RESULTING IN DEATH.†

By SAMUEL SEXTON, M. D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

Grave and even fatal ear disease in early life is of much more frequent occurrence, probably, than is generally suspected. Inflammation of the middle-ear tract may thus arise from head catarrh or other cause and rapidly extend itself to the dura mater without the warning usually given by the occurrence of a discharge from the external auditory canal. Or the discharge, once established, may suddenly cease because of the closure of the outlet through the drum-head, the secretions escaping *via* the Eustachian tube, which is proportionately very large in infancy. The causes of special danger will be alluded to farther on.

In the two following cases, occurring in very young infants, however, early evidence was not wanting, even to the inexperienced, of serious aural trouble, and death was due to their neglect and ill-directed treatment.

Case I.—*Otitis Media Purulenta; Polypus; Facial Paralysis; Pachymeningitis; Death.*—N. N., of Jewish parentage, aged six months, was brought to my clinic at the New York Eye and Ear Infirmary, in March, 1884, with the following history: When three months old he was exposed to a draught coming through an open window while traveling in a railway carriage. A few days afterward a circum-auricular swelling was observed to take place, which was, by order of the attending physician, poulticed with chamomile flowers, hops, and Indian meal for three weeks continuously. The purulent matter which had been collecting was then liberated with a lancet. After discharging a week the opening was allowed to close, but subsequently it was again opened and dressed with a tent and some antiseptic salve. The ear and wound were syringed three times a day with an aqueous solution of one drachm of carbolic acid to the pint—the solution passing freely through from the wound into the canal. This treatment had been persisted in until the date of coming to the infirmary. The child's mother thinks two considerable-sized sequestra were removed by the syringing about four weeks ago. The discharge, it is alleged, varies from time to time, and is now absent. The child nurses well and sleeps fairly well.

Examination.—The lumen of the external auditory canal is obstructed with pus, the removal of which brings to view a large polypoid growth which fills the canal.

There is partial right facial paralysis.

March 13th.—Discharge from the ear and sinus more free to-day, but the child is restless. The polypus was removed by Sexton's snare. It was found to be of much greater size than had been expected, filling the tympanum and canal almost to the meatus externus. It was about half an inch in length and somewhat nodulated. There was free hæmorrhage after avulsion, which was, however, soon arrested by instillations of hot water.

The treatment consisted in gentle cleansing with warm water as required, afterward dressing the parts with calendula and boric acid. Internally the calcium sulphide in small doses was given several times daily.

15th.—There is diminution in the quantity of the discharge, which is less purulent. General appearance is better, and the restlessness which existed before the operation is less.

I did not again see the patient; his mother, however, came several months after to the infirmary to report his death. She said that the next day after his last visit he became more restless, had a cough, and raised mucus. Vomiting occurred after nursing or taking food or medicine, and continued until death, which took place on April 5th. The child ceased to nurse three days before death, and for two days no discharge from either the meatus or sinus was observed. He had *convulsions* for two weeks, at the beginning of which "his face became straight again" (double facial paralysis), and at the end there was strabismus. These symptoms, taken together with the previous history, point to pachymeningitis. It seems probable that the

* The addition of a small proportion of glycerin to the solutions used for impregnating the wood-flour and sawdust will prevent the tendency of the latter to fly about when handled.

† Read by title at the annual meeting of the American Otological Society, July 14, 1885.

rapid recurrence of the polypoid growth, blocking up the outlets and preventing drainage, may have hastened the result. The physician who attended the patient at home certified that he died of "pneumonia, convulsions, and dentition."

The apparent absence of suffering during the early part of the progress of the disease is noteworthy. There was no autopsy.

The polypus removed was examined by Dr. Frank Ferguson, and found to be a myxo-fibroma. The following are the notes of the examination:

The tumor is covered throughout by mucous membrane, excepting at the points of attachment. Covering this mucous membrane, near the points of attachment, are laminated cylindrical cells. In the same region the mucous membrane is arranged in large papillæ, which can be seen with the naked eye. Elsewhere the surface of the tumor is smooth and covered by flat epithelium. Beneath the mucous membrane are large numbers of round cells. The center of the tumor is composed of fibrillated and granular material, numerous small round cells, and mucous corpuscles. The vascular supply is abundant.

Case II.—*Otitis Media Purulenta, complicated with Lymphadenoma of the Neck, resulting in Caries of the Atrium, Attic, Antrum, Tympanic and Auditory Plates; Facial Paralysis, Purulent Meningitis; Death; Autopsy.*—Albert S., a mulatto, aged seven months. The patient was brought to the New York Eye and Ear Infirmary in June, 1885, with the following history:

Three months previous to this date a small swelling appeared in front of the left tragus, coincident with a purulent discharge from the left ear. The swelling extended downward, rapidly enlarging, forming a large, irregular mass, occupying the whole of the left side of the neck. One month ago the otorrhœa ceased almost entirely, and at the same time the child was taken to a city dispensary and placed under local and general medicinal treatment for the glandular tumor. During this period of treatment the tumor fluctuated in size, a discharge appeared in the right ear, and the child became very restless and irritable, sleeping poorly, attacks of vomiting alternating with diarrhœa; and left facial paralysis was noticed for the first time.

Examination, June 1st.—The left meatus was occluded by granulation tissue, which was removed, giving vent to a large quantity of very offensive purulent matter. The canal was dilated, the posterior and inferior walls presenting an ulcerated granular surface, the drum-head was entirely destroyed, and the tympanum presented a large cavity caused by the necrotic destruction of portions of the *annulus tympanicus* and temporal plate, the inner wall of the attic and atrium, the antrum and auditory plate. In a word, the bony walls of the large pathological cavity thus exposed to view were denuded in every direction; the ossicles were absent, with the exception of the stapes, which could be seen lying loosely upon the upper and posterior part of the inner wall. The right meatus was filled with granulation tissue which sprouted from the walls of the canal, the drum-head was destroyed, and denuded bone could be detected with the probe in any portion of the tympanum. On the left side of the neck there were a number of lymphadenomata aggregated together, forming a large, irregular tumor, limited above by the inferior attachment of the auricle, and below by the level of the thyroid gland. No fluctuation could be detected in any portion of the mass. There was complete left facial paralysis.

Treatment.—Small and frequently repeated doses of the tincture of aconite and calcium sulphide were given, the canals being cleansed and powdered boric acid insufflated once daily. During the next eight days the patient's condition improved somewhat.

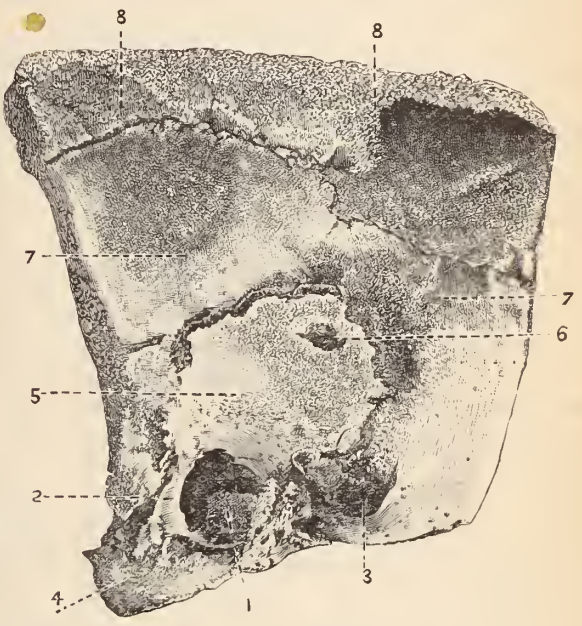
June 8th.—Restless and irritable, with some febrile movement; temperature 102°; vomiting frequently. Discharge from ears free.

10th.—The patient became drowsy and stupid, and had general convulsions. Coma supervened, and he died June 12th.

Autopsy.—The dura mater is healthy, with the exception of that portion covering the superior surface of the left petrous bone, which is much thickened from the deposit of neoplastic tissue, and at points presents isolated centers of ossification.

There is purulent meningitis of the convexity, the deposit of lymph being more particularly noticeable along the margins of the longitudinal fissure and on the under surface of the anterior and posterior cerebral lobes. The cortical substance is quite soft, and there is considerable accumulation of greenish offensive matter in the subarachnoidean cavity. No connection could be traced between the ear and glandular enlargement on the neck.

The accompanying wood-cut, somewhat enlarged, shows the outer surface of the left temporal bone after the specimen had been prepared. The absence of the osseous portion of the external auditory canal at this age brings the inner wall of the tympanum, which is very large, well into view; 1 is the promontory of the inner wall, and just above it is the foramen rotundum from which the stapes has escaped. The inner wall of the attic was gone, exposing the horizontal semicircular canal. The walls of the antrum and the adjacent cellules were eroded away and the entire auditory plate was honey-combed. The auditory plate, 5, which was scarcely united to the squamous and mastoid portions, was undergoing sequestration, entirely denuded, and a sinus, 6, afforded communication between the antrum and an abscess beneath the periosteum.



The annulus tympanicus composing the anterior wall of the external auditory canal is shown at 2; it is roughened all around, as is the tympanic plate itself. The rudimentary mastoid process is seen at 3; the under surface of the petrous bone at 4. The squamous portion is shown at 7, 7; the parietal bone at 8, 8.

On the inner surface of the specimen, not shown in the cut, is seen an extensive opening along the line of the petro-squamosal suture through which, probably, the inflammatory process extended to the dura.

It is probable that in this case the inflammation extended itself from the tympanum along underneath the auditory plate into the antrum, while a periostitis externa manifested itself on the outer surface.

Remarks.—In reviewing Case I, it seems remarkable that so little nervous irritability existed during the progress of the case, although the ear was deeply attacked. With the exception of the last two or three weeks, the child suffered but little, and, so far as pain was concerned, it may not have seemed important to the ordinary observer.

To the retention of secretions, the formation of which was actively promoted by the three weeks' persistent poulticing, and perhaps also to the vigorous syringing, was doubtless largely due the gravity of this case.

Although the treatment of a case in this advanced stage is somewhat expectant, yet it is generally best to administer frequently small doses of pulsatilla or aconite during the active progress of the disease in order to allay nervous irritability.

Acute aural inflammation in children often gives rise to symptoms well calculated to puzzle the general practitioner; and hence its presence is liable to be unsuspected; thus, in Case I, the alleged cause of death as reported to the Bureau of Vital Statistics did not include the aural trouble.

When the proportionately large area of the middle-ear tract in children is considered, one need not experience any surprise at the frequency of its invasion by disease. The tympanum, antrum, and Eustachian tube thus comprise a very much exposed region which occupies a dangerous proximity to the dura mater—being separated by an extremely thin plate of bone, often imperfectly closed by osseous tissue especially along the line of the petro-squamosal suture. Free vascular communication is afforded through this thin partition between the middle ear and the dura, and, in any inflammatory process in either, the other is extremely liable to be affected.

The important knowledge to be obtained by observing the phenomena manifesting themselves in the ear in children is not available always without an expert examination; and this becomes a much more difficult matter when exterior manifestations are wanting, since deafness and distressing autophonia, etc., can not always be explained by children, and never by very young infants, and pain in such cases may be relegated to another region. Although recovery may take place when the aural symptoms are not recognized, yet deafness may remain.

Too much stress can not be placed on the advisability of avoiding a meddlesome and heroic plan of treatment, often practiced that "something may be done."

In these neglected cases it is well to remember that the danger does not lie in an invasion of the mastoid cellules, since the mastoid process exists in a rudimentary state only before the age of puberty, but in an extension of the inflammatory process to the antrum, caries of the bone being consecutive thereto. An independent but coincident attack of periostitis externa may indeed take place. Where the latter occurs alone, recovery is usually much more rapid, since, under proper treatment, reabsorption of pus takes place, or it is evacuated by the knife.

Sometimes large sequestra, consisting of portions of the auditory or tympanic plate, or of portions of bone containing the cochlea or semicircular canals, are removed after sequestration in these cases, especially in broken down or scrofulous subjects. It is surprising to witness the rapidity with which recovery often takes place after the detachment of very large pieces of temporal bone. Officious surgical meddling in these cases can but be most injurious, since it is not wise to attempt to separate sequestrating from healthy bone until Nature has completed her share of the process. We have our hands full, generally, in the effort to maintain proper drainage. I have of late found strands of antiseptic catgut, as prepared by Mr. Am Ende, of Hoboken, introduced into either the sinus which usually exists behind the auricle, or into the external auditory canal, a very effective means of drainage. Beyond this, and dressings consisting of boric acid and calendula locally, I have found it a good plan to let the ear alone and treat the patient.

I am indebted to my assistants, Dr. William A. Bartlett and Dr. Robert Barclay, for the admirable care which these patients received while under observation. To them I am also indebted for the notes of the post-mortem of Case II, which was under Dr. Bartlett's charge.

A CASE OF MELANO-SARCOMA OF THE NOSE CURED BY GALVANO-CAUTERIZATION.*

By R. P. LINCOLN, M. D.,
NEW YORK.

In November, 1884, Mrs. L. presented herself for consultation, and supplied the following history:

In August, 1882, she first noticed an obstruction to free respiration in the right nostril, and about the same time was annoyed by a continual muco-purulent, blood-stained discharge from the same nostril. There was also matter of a similar appearance which was expectorated, and which evidently came from the posterior nares.

Her general health at this time was good, and there was little or no pain.

It was not till the following winter that this nostril became completely occluded, when operative interference was decided upon.

Dr. D. Hayes Agnew, of Philadelphia, removed the growth April 2, 1883. After a microscopic examination, he announced its character as "cancerous." After a period of about two months a repetition of the former symptoms manifested themselves; these continued to increase until November following, when Dr. Agnew repeated his first operation.

A few months of uncertainty succeeded the second operation, but frequently recurring hæmorrhages and renewed difficulty in breathing gave assurance of a recurrence of the tumor until February, 1884, when the growth seemed to increase very rapidly. At this time the patient placed herself under the care of a physician in Rome, in this State, a man of much repute among the people, who used, in the words of the patient, "plasters and pastes" for about two months, when he confessed his inability to remove the trouble. Notwithstanding this treatment, the tumor continued to grow.

---

* Read before the American Laryngological Association, June 25, 1885.

On examining the patient, I found the right side of the nose, extending well up to the inner canthus of the eye of the corresponding side, enlarged, the fullness amounting to about four times the size of the left side of the nose.

The lower half of its ala was wanting, the remaining border being puckered, somewhat contracted, and of a purple color, which gradually faded until the integument was of normal appearance half way up this side of the nose. There protruded from this nostril, about half an inch, a dark-colored, fleshy mass completely filling it; this was attached to the outer margin of the nostril as well as to its floor. A plum-colored discharge was constantly flowing from the nostril, and the lightest touch of the mass with a probe was followed by dark grumous blood. A further careful exploration showed the tumor to grow from the lower and middle turbinated bones, and from the floor of the nostril for a distance of two inches and a half. The septum was free.

A rhinoscopic examination disclosed the tumor protruding into the post-nasal cavity and occupying about half of it. I proposed a removal of the growth with the galvano-cautery écraseur and a subsequent cauterization of points of attachments as offering the best chance of relief.

November 18, 1884, the patient submitted to operation, Dr. Delavan and Dr. Goodwillie being present and kindly giving their assistance. The patient being etherized, I passed the platinum-wire loop of the galvano-cautery écraseur about the tumor at its attachments and thus separated it.

Immediately afterward the seat of the growth was thoroughly cauterized. The loss of blood was inconsiderable. For a week after the operation a solution of bicarbonate of sodium and carbolic acid was injected into the nostril many times a day; after this an ointment containing two grains of iodoform to an ounce of vaseline was applied to the healing surface three times a day.

Two weeks after the operation the patient was permitted to go to her home in Pennsylvania, with no diseased point discoverable and with perfectly free respiration through the nostril.

May 27, 1885.—The patient returned at intervals of one or two months, the last time on this date, for observation. No further treatment has been necessary, as the parts are perfectly healthy. The integument, formerly discolored, has assumed a normal appearance. The remaining deformity is hardly noticeable, far less than the most hopeful would have expected.

I present herewith a specimen of the tumor mounted for microscopic examination, together with a report of the microscopic appearance, both of which were made by my friend Dr. Frank Ferguson.

His report I quote:

"The cut surface is dark, with small areas of dark gray and flesh-colored tissue. Under the microscope the portion of the tumor which is flesh-colored is composed of round and ovoid cells of medium size. The cells are close to each other and distinctly nucleated. The darker portions of the tumor are hæmorrhages. The areas of dark gray are composed of large flat cells deeply pigmented. The cells are supported by a stroma of fibrillated and granular material. There are numerous large vessels seen throughout the tumor, some of them with thick walls; also a few gland-ducts, probably the remains of glands belonging to the tissue in which the growth originated.

"There are numerous hæmorrhages throughout the entire tumor, in some places large, in other places punctate. Prognosis *grave*."

Note.—Information received from the patient October 1st showed that there were no indications of a return of the disease.

Book Notices.

A Treatise on Nervous Diseases; their Symptoms and Treatment. A Text-book for Students and Practitioners. By Samuel G. Webber, M. D., Clinical Instructor in Nervous Diseases, Harvard Medical School, etc. New York: D. Appleton & Co., 1885. Pp. ix–415.

There has long existed a demand for a concise and definite statement of the elements of neuro-pathology and therapeutics. The student about to begin the study of neurological medicine is confronted by a literature of ominous extent, in the mazes of which he is ill-prepared to tread without the aid of personal tutelage. In Germany this condition of affairs has been recognized, as a number of little text-books bear witness; but in this country and England the want has been but inadequately met. We have very complete treatises, it is true, as well as monographs of no mean value; and yet the fact remains that, until the advent of the little book before us, the profession has been without a concise statement of the elements of neuro pathology.

In the face of this obvious deficiency, Dr. Webber's little book comes to us as a welcome addition to our library. To those who are unable to attend the special clinics of a large city, and who are, nevertheless, desirous of acquiring a knowledge of the principles of neuro-diagnosis, it will undoubtedly render good service. As an introduction to a course of special reading it is also well adapted. Thus, in the beginning of the book will be found a brief statement of the practical points of cerebral anatomy and physiology; and this theoretical portion of the volume is immediately followed by a section of considerable extent treating of the analysis of symptoms. We then come to the chapters on special cerebral diseases. These are handled in a terse manner, the author giving what he considers are the essentials of diagnosis and therapeutics.

The chapters on the diseases of the spinal cord are written in the same practical spirit, and, like those on cerebral pathology, are preceded by a concise statement of the essential anatomical and physiological questions involved.

In the latter half of the volume the diseases of the peripheral and sympathetic nerves receive attention.

None of the subjects brought forward are treated of exhaustively; nor can the author be justly taken to task for superficiality, since his very object is conciseness. Enough that he has fulfilled his task in a manner which leaves nothing to be desired.

We have no hesitation in recommending this admirable little book to students and practitioners alike.

BOOKS AND PAMPHLETS RECEIVED.

Medical Communications of the Massachusetts Medical Society, Vol. xiii, No. 5, 1885. Boston: Printed by David Clapp & Son, 35 Bedford Street, 1885. Pp. 321–501. And Proceedings of the Councillors. Pp. 85–113.

Proceedings of the Connecticut Medical Society, 1885. Ninety-fourth Annual Convention, held at Hartford, May 27th and 28th. New Series, Vol. iii, No. 2. Published by the Society, S. B. St. John, M. D., Secretary. Hartford, Conn.: Press of Case, Lockwood, and Brainard Company, 1885. Pp. 3–239.

Vaginal Hysterectomy for Cancer. By A. Reeves Jackson, A. M., M. D., Professor of Gynæcology in the College of Physicians and Surgeons of Chicago, etc. Read in the Section of Obstetrics and Gynæcology at the Thirty-sixth Annual Meeting of the American Medical Association. [Reprinted from the "Journal of the American Medical Association."]

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, OCTOBER 10, 1885.

THE AMERICAN MEDICAL ASSOCIATION'S NEW COMMITTEE'S SUB-COMMITTEE.

It seems that what was said to be sauce for the goose is not considered to be sauce for the gander. In April the Lacedæmonian cry went up that the committee that was originally intrusted with the organization of the Ninth International Medical Congress was merely authorized to carry out the will of the American Medical Association, and that its work was in every respect subject to the revision of the association. This cry carried the day, and the New Orleans meeting proceeded to revise the committee's arrangements with a vengeance—with what results, the country is but too well aware. The association's pet committee, however — those gentlemen who were chosen to supersede the legitimate body—soon found that there was no further occasion for the responsibility alleged by the New Orleans meeting; or, rather, it is a sub-committee that has made that discovery.

Our readers will remember that the reconstructed committee held a meeting in New York on the 3d and 4th of September, at which a sub-committee, styled an executive committee, was constituted, and that the further prosecution of the work of patching up the organization of the Congress was given into the hands of this sub-committee. The "Journal of the American Medical Association" now informs the world that the executive committee held a meeting in New York on the 24th of September, at which, "more than a quorum" being present, it perfected its organization by electing Dr. Henry H. Smith, of Philadelphia, chairman, and Dr. Frederic S. Dennis, of New York, associate secretary-general, after which, "to prevent all further misunderstanding, both at home and abroad," it unanimously adopted the following remarkable resolution: "*Resolved*, That this executive committee enters upon the management of the affairs of the Ninth International Medical Congress with the understanding that, in accordance with rule No. 10, its powers are not restricted except by the rules and regulations adopted September 3, 1885, by the committee of arrangements appointed by the American Medical Association in April, 1885; and that the actions of this executive committee are final, not being subject to revision, amendment, or alteration by either the committee of arrangements or the American Medical Association."

Indeed! Is this "understanding" supported on an opinion by Speaker Randall? And if, in this instance, not only is the so-called "committee of arrangements" not subject to oversight by the organization that appointed it, but even a sub-committee is answerable neither to it nor to its creator—nor, in fact, to any power on earth—we would like to know how Mr. Randall likes the tricks and the manners of the coterie whom he so kindly accommodated with his opinion in the early part of the summer.

For our part, we are perfectly well satisfied. We have all along maintained that the original committee ceased to be a committee of the American Medical Association the moment its invitation was accepted at Copenhagen, and that at the same moment it became, by adoption, a committee of the Congress, responsible to it, and to it alone. As a legitimate corollary of that position, we have held that the original committee was under no sort of obligation to report to the New Orleans meeting. We are able to say now that such indeed was the conviction of the truly representative men in the old committee, but that they were seduced into a course of conduct that was urged upon them as being in the interest of conciliation, whereas no real conciliation was ever intended by the seducers. The sub-committee is now quite of our way of thinking—*mutatis mutandis;* and we wish it joy.

MINOR PARAGRAPHS.

THE PROPOSED NEW NATIONAL MEDICAL ASSOCIATION.

We would call attention to a letter, signed "Subscriber," which we publish in another column, and beg to assure our readers that the writer of the letter is a gentleman who has paid a good deal of attention to matters connected with medical organizations, and has on more than one occasion given evidence of a willingness to sacrifice his own favorite projects when convinced that the welfare of the profession would be better served by the substitution of other measures. It will be seen that the plan he now brings forward gives abundant scope for the settlement of details in a leisurely way, which is certainly wise and conservative. The point on which most solicitude ought to be felt seems to us to be the manner of constituting men members of the association. That is the rock on which the American Medical Association has struck. At first, its members were the representative men of the profession, but, as fresh delegations were eligible year after year, a less and less representative set was chosen, until finally the organization became utterly unworthy of its early history, and ceased to enjoy the confidence of the profession.

TULIT ALTER HONORES.

In a review of the first volume of Pepper's "System of Medicine," the "Lancet," of London, says:

"Variola, Vaccinia, and Varicella have been intrusted to the pen of Dr. James Nevins Hyde." . . . "The writer's article on Vaccinia strikes us as one of the most candid and lucid that have been written upon this much-discussed topic. He is not so blind as to refuse to grant that vaccination sometimes fails to protect, but he rightfully declaims against the tendency to irrational generalization which sees in this fact the condemnation of the practice. His statement appears to us as particularly fair—viz., that 'vaccination almost invariably protects against small-pox for the time being; generally for a long term of years; sometimes for a lifetime. Often the protection is absolute; as a rule it is very nearly so; in rare instances it is trifling.' Again, in dealing with the complications of vaccination, he takes up a very candid position with regard to the risks of erysipelas, of vaccinal syphilis, etc. He declares in favor of bovine over humanized virus after a full discussion of the arguments on either side, saying that 'in barely one particular—that of promptness of action—can humanized virus justly be credited with any superiority, while in every other essential respect it is inferior, so far

as any difference is to be observed.' At the same time he does not admit that there is any proof of the deterioration of the Jennerian vaccine."

Praise and blame deserved but withheld are about even in most men's lives. We trust, therefore, that we shall not be looked upon as actuated wholly by considerations of *meum* and *tuum* if we state that, of the three articles mentioned by the "Lancet," the one on Vaccinia was written, not by our excellent friend Dr. Hyde, but by the editor of this journal.

THE STATE OF NEW YORK AND THE CANADIAN SMALL-POX EPIDEMIC.

Last winter the accidental Governor of the State of New York, who is now a candidate for re-election, distinguished himself by, *inter alia*, pandering to the rage for a penny-wise and pound-foolish economy by refusing to sign a bill appropriating the inconsiderable sum of fifteen thousand dollars for the use of the State Board of Health in case of emergency. At the time, we pointed out the criminal foolishness of the Governor's course. The emergency is now upon us, for there is every reason to apprehend that the Canadian outbreak of small-pox will cross the frontier unless the most energetic precautions are taken. Unless the people of the State are willing to submit to the inconvenience of an extraordinary session of the Legislature, we know not how they can be defended, save at the far greater expense of sucking Government pap—an expense to their honor that will not tally well with their past record. Already the apprehension felt in Buffalo, together with the rumors of outbreaks at Rouse's Point and other localities, can not be viewed otherwise than as disquieting.

A DANGER TO THE ARMY MUSEUM AND LIBRARY.

Some anxiety has been expressed—although not publicly, so far as we know—lest the operation of the general order limiting the time for which officers of the army could be stationed in Washington should involve the removal of Dr. Billings from the further prosecution of the grand work upon which he has spent so many years. That work is still far from being finished, and we can not see how the public interests could fail to suffer by Dr. Billings's transfer to another field of duty. It is not to be wondered at, therefore, that the possibility of such an occurrence should be looked upon with alarm. There can be no doubt, however, that it can be avoided without violation of the spirit of the order, and we are convinced that there can be little less doubt that the Government will take good care that it is avoided. We look, then, to see Dr. Billings continued in the sphere which he has so adorned, and we are sure that such a course is earnestly desired by the profession.

NEWS ITEMS, ETC.

The New York Quarantine Service.—The service in the Lower Bay was discontinued on the 1st of October, a month earlier than usual, owing mainly, it is said, to the comparative freedom of Havana and other tropical ports from yellow fever.

The Health of the State of New York.—The State Board of Health's "Monthly Bulletin" for the month of August shows a reported mortality of 7,284, which is considerably lower than that for July. But this, it is explained, is partly accounted for by the failure to receive reports from Buffalo, Long Island City, and a number of large villages. The percentage of infant mortality was 46·73. Zymotic diseases caused 337·31 deaths in every 1,000, diarrhœal diseases 236, consumption 128·87, and acute respiratory diseases 57·52. The board has issued a most useful circular on the prevention of small-pox, setting forth the laws on the subject, and giving information as to the general management of an outbreak.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 6, 1885:

DISEASES.	Week ending Sept. 29.		Week ending Oct. 6.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	39	16	46	8
Scarlet fever	15	2	19	2
Cerebro-spinal meningitis	2	2	1	1
Measles	4	0	3	1
Diphtheria	39	19	28	8
Small-pox	3	3	6	0

Precautions against Small-pox.—The Board of Health of Fall River, Mass., has accepted an offer from the New Hampshire State Board of Health, which proposes to issue tickets of inspection to all persons from the infected Canadian districts who pass through the State *en route* for Fall River. The tickets will indicate whether the holders have been vaccinated; and, if a passenger from Canada can not produce a ticket, the inference will be that he has thrown it away, and he will accordingly be quarantined, unless he can account for its absence. The medical inspector at Fall River will vaccinate all who need it, and the most rigorous measures will be enforced to prevent the introduction of the disease into the city.

The Contagious Pleuro-pneumonia of Cattle is reported to have been wholly suppressed in Illinois, and the Governor of that State will therefore shortly take steps toward securing a discontinuance of the quarantine measures adopted in other States.

The Management of the Montreal Small-pox Epidemic having been offered to Dr. Edwin M. Snow, of Providence, Rhode Island, that gentleman is reported to have accepted the offer conditionally.

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, September 30th: *Montreal, Canada.*—For the week ending September 29th: 297 deaths from small-pox occurred in Montreal during the week. From September 26th to 29th, inclusive, there were 48 deaths from small-pox in the towns adjoining the city. The official reports give the following record of deaths from the disease in Montreal to September 23d: In April, 6; May, 10; June, 13; July, 46; August, 239; September 1st to 22d, inclusive, 524. Total to that date, 838. The disease has spread with great rapidity during September. During the first five days the deaths were 77; for the week ending 12th, 128; six days and a half ending 18th, 184; September 19th to 22d, inclusive, four days, 135. *Three Rivers, Canada.*—For the week ending September 26th: 5 cases and 1 death from small-pox; disease spreading through the villages in the consular district. *Toronto, Canada.*—September 30th: No new cases reported. *Havana, Cuba.*—For the two weeks ending September 24th: 47 cases and 20 deaths from yellow fever. *Cardenas, Cuba.*—September 19th: Free from epidemic diseases. *Matanzas, Cuba.*—September 23d: Intermittent fever prevalent. *San Domingo.*—September 14th: Free from epidemic diseases. *London, England.*—For the week ending September 14th: 9 deaths from small-pox, including 6 of London residents who died outside of the registration district. *Paris, France.*—For the week ending September 12th: 7 deaths from small-pox; 34 cases treated in hospital. *Bordeaux, France.*

—For the week ending September 19th: 4 deaths from small-pox. *Barcelona, Spain.*—September 1st to 10th: 623 cases and 302 deaths from cholera; disease assuming a milder form. *Cadiz, Spain.*—September 12th: Total mortality 155, average 40; excess attributed to cholera. *Santander, Spain.*—September 19th: Cholera decreasing. *Gibraltar, Spain.*—By telegram September 30th: Authorities to-day issue clean bills of health. *Valencia, Spain.*—September 5th: Cholera decreasing; no new cases in the village during the week. *Genoa, Italy.*—September 13th: 1 death from small-pox. *Venice, Italy.*—For the week ending August 29th: 6 deaths from small-pox. *Palermo, Italy.*—September 18th: Consul reports cholera increasing, and states that about forty thousand of the inhabitants have fled from the city. *Trieste, Austria.*—For the week ending September 12th: 13 cases and 4 deaths from small-pox. *Antwerp, Belgium.*—For the week ending September 12th: 4 cases of small-pox. *St. Petersburg, Russia.*—For the week ending September 12th: 1 death from small-pox. *Warsaw, Russia.*—For the week ending September 12th: 2 deaths from small-pox. *Calcutta, India.*—For the week ending August 22d: 14 deaths from cholera. *Colombo, Ceylon.*—For the week ending August 22d: 44 cases and 18 deaths from cholera *Guaymas, Mexico.*—September 23d: Consul reports yellow fever increasing and becoming more virulent; 138 cases and 36 deaths from the disease since September 1st; it has also appeared at *Hermosillo. Mazatlan, Mexico.*—September 15th: Consul reports yellow fever present in sporadic cases; statistics of deaths can not be obtained; authorities continue to issue clean bills of health. During August 28th, 29th, and 31st, and September 1st and 2d (the report for August 30th has not yet been received), there were in Spain 17,147 cases of cholera and 5,466 deaths. The total number of cases and deaths from March 4th to September 2d is 232,105 cases and 86,692 deaths.

Personal Items.—The "Medical Times," of Philadelphia, announces that Dr. George M. Sternberg, of the army, has been elected an honorary member of the Royal Academy of Medicine, of Rome; also that the following changes in the residences of Philadelphia physicians have been made: Dr. Roberts Bartholow to 1525 and 1527 Locust Street, Dr. Theophilus Parvin to 1718 Walnut Street, Dr. Charles K. Mills to 1909 Chestnut Street, and Dr. B. F. Baer to 2010 Chestnut Street, and that Dr. J. M. Holland has taken an office at No. 1914 Rittenhouse Square. Professor McCall Anderson sailed from New York by the Servia, Dr. Charles E. Sajous, of Philadelphia, by the Westernland, and Dr. W. L. Ranney, of New York, by the Adriatic, last week. The list of arrivals from abroad during the same week included the names of Dr. Major, of Montreal, Dr. G. H. Lyman, of Boston, and Dr. G. G. Wheelock, of New York. Our readers will be glad to learn that Dr. Fordyce Barker has so far recovered his health as to be able to make a visit to Boston.

An Attempt to "Boycott" a Physician is reported from Elizabeth, New Jersey. According to the newspaper accounts, a Roman Catholic priest denounced the physician from the pulpit as an apostate, and warned his parishioners against employing him, threatening them with a refusal to perform the offices of the Church in their behalf in case they disobeyed the warning.

The Johns Hopkins University School of Medicine.—The Baltimore correspondent of the Philadelphia "Medical Times" states that it is rumored that Professor Matthew Hay, of Edinburgh, has been elected professor of pharmacology.

A Museum of the Vegetable Materia Medica.—We learn that Messrs. Parke, Davis, & Co., of Detroit and New York, are prepared to furnish students with a very complete set of specimens of the crude vegetable drugs, arranged within a moderate compass, with each specimen numbered to correspond with a printed list. The value of such a collection to students of materia medica can not well be over-estimated, and the price asked ($10) is so low as to bring it within the reach of all.

An Honor to a Physician.—The "Union médicale" states that, on the recommendation of the director of the Bourboule Spring, the municipal authorities of the place have decided to name one of the principal streets for the late Dr. Noël Gueneau de Mussy, who took a prominent part in bringing the virtues of the Bourboule waters into notice.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 27 to October 3, 1885:*

McParlin, T. A., Colonel and Surgeon. Directed to transfer his duties and the public funds for which he is accountable, as Assistant Medical Purveyor, to Captain Henry Johnson, Medical Storekeeper, who will, in addition to his present duties, temporarily perform the duties of Assistant Medical Purveyor, New York city. S. O. 223, A. G. O., September 29, 1885.

Caldwell, D. G., Major and Surgeon. Ordered from Fort Laramie, Wyoming, to Fort D. A. Russell, Wyoming. S. O. 97, Department of the Platte, September 28, 1885.

Bartholf, J. H., Captain and Assistant Surgeon. Ordered from Fort Ringgold, Texas, to Fort McIntosh, Texas, for duty as Post Surgeon. S. O. 125, Department of Texas, September 28, 1885.

Brechemin, Louis, Captain and Assistant Surgeon. Ordered from Fort D. A. Russell, Wyoming, to Fort Laramie, Wyoming. S. O. 97, Department of the Platte, September 28, 1885.

Macauley, C. N. B., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort A. Lincoln, Dakota Territory, and ordered for duty at Camp Poplar River, Montana Territory. S. O. 105, Department of Dakota, September 21, 1885.

Knudler, William L., First Lieutenant and Assistant Surgeon. When relieved from duty at Camp Poplar River, Montana Territory, by Assistant Surgeon Macauley, to report to commanding officer, Fort Snelling, Minnesota, for duty. S. O. 105, Department of Dakota, September 21, 1885.

Wales, P. G., First Lieutenant and Assistant Surgeon. Relieved from temporary duty at Boisé Barracks, and ordered for duty at Fort Cœur d'Alène, Idaho. S. O. 160, Department of Colorado, September 21, 1885.

Ewing, C. B., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Stanton, New Mexico, and ordered for duty at Fort Leavenworth, Kansas. S. O. 147, Department of the Missouri, September 25, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 3, 1885.*

Jones, William H., Surgeon. Ordered to Navy-Yard, League Island, Pa., October 15th, as the relief of Medical Inspector M. Bradley.

Bradley, Michael, Medical Inspector. Detached from Navy-Yard, League Island, Pa., October 15th, and placed on waiting orders.

Owens, Thomas, Assistant Surgeon. Ordered to Naval Station, New London, Conn., as the relief of Surgeon William A. Corwin.

Corwin, William A., Surgeon. Detached from Naval Station, New London, Conn., and ordered to the U. S. Steamer Adams, October 31st.

MAGRUDER, A. F., Surgeon. Ordered to the U. S. Steamer Yantic, without delay, as the relief of Surgeon H. L. Law.

LAW, H. L., Surgeon. Detached from the U. S. Steamer Yantic, and wait orders.

SIMON, W. J., Surgeon. Detached from the Naval Academy, October 1st, and wait orders.

DRENNAN, M. C., Surgeon. Detached from the Naval Academy, October 1st, and wait orders.

CABELL, ARTHUR G., Passed Assistant Surgeon. Assigned to the U. S. Steamer Adams, October 31st.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the week ended October 3, 1885.*

BAILHACHE, P. H., Surgeon. Detailed as chairman of board for the physical examination of officers of the Revenue-Marine Service. September 28, 1885.

VANSANT, JOHN, Surgeon. Order to New Orleans, La., revoked. To proceed to St. Louis, Mo. October 2, 1885.

PURVIANCE, GEORGE, Surgeon. To proceed to Louisville, Ky., as inspector. October 1, 1885.

GASSAWAY, J. M., Surgeon. Detailed as chairman of board for the physical examination of officers of the Revenue-Marine Service. October 3, 1885.

GODFREY, JOHN, Surgeon. Order of September 16th amended. To proceed without delay to Louisville, Ky. September 28, 1885.

GOLDSBOROUGH, C. B., Passed Assistant Surgeon. Order of September 16th amended. When relieved, to proceed to Chicago, Ill. October 1, 1885.

IRWIN, FAIRFAX, Passed Assistant Surgeon. Detailed as recorder of board for the physical examination of officers of the Revenue-Marine Service. September 28, 1885. To examine physically and instruct crews of the Life-Saving Service, Third District, in the method of restoring the apparently drowned. October 3, 1885.

BANKS, C. E., Passed Assistant Surgeon. Detailed as recorder of board for the physical examination of officers of the Revenue-Marine Service. October 3, 1885.

Society Meetings for the Coming Week:

MONDAY, *October 12th:* New York Ophthalmological Society (private); New York Medico-Historical Society (private); New York Academy of Sciences (section in Chemistry and Technology); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club; Norwalk, Conn., Medical Society (private).

TUESDAY, *October 13th:* New York Medical Union (private); New York Surgical Society; Medical Societies of the Counties of Rensselaer, Chenango (tri-annual), Greene (semi-annual, Cairo), Jefferson (quarterly, Watertown), Oneida (quarterly, Utica), and Tioga (Owego), N. Y.; Newark, N. J., and Trenton, N. J., Medical Associations (private); Medical Societies of Bergen and Cumberland (semi-annual) Counties, N. J.; Medical Society of Litchfield County, Conn. (annual).

WEDNESDAY, *October 14th:* New York Pathological Society; American Microscopical Society of the City of New York; New York Medico-Legal Society; Medical Society of the County of Cayuga, N. Y.; Tri-States Medical Association (Port Jervis, N. Y.); Pittsfield, Mass., Medical Association (private); Franklin (quarterly, Greenfield), Hampshire (quarterly, Northampton), Middlesex South (Cambridge), and Plymouth (special), Mass., District Medical Societies; Vermont State Medical Society (annual, Montpelier); Philadelphia County Medical Society (conversational).

THURSDAY, *October 15th:* New York Academy of Medicine; New Bedford, Mass., Society for Medical Improvement (private).

FRIDAY, *October 16th:* Chicago Gynæcological Society (annual).

SATURDAY, *October 17th:* Clinical Society of the New York Post-Graduate Medical School and Hospital.

OBITUARY NOTES.

John Light Atlee, M. D., of Lancaster, Pa., died at his home in that city on Thursday, October 1st, in the eighty-sixth year of his age. He was born in Lancaster, November 2, 1799, and received his medical degree from the Medical Department of the University of Pennsylvania in 1820. He was one of the founders of the Medical Society of the State of Pennsylvania, and was chosen president of the society in 1857. He was also one of the original members of the American Medical Association, of which he was president in 1882. In 1877 he was elected an honorary fellow of the American Gynæcological Society. On the union of Franklin and Marshall colleges, he was appointed to the professorship of anatomy and physiology, which he held until 1869. During the greater part of his long career he held a number of positions of trust not connected with medicine, and was specially interested in the public schools of Lancaster. In connection with his brother, the late Dr. Washington L. Atlee, he was for many years widely known as a successful ovariotomist, and he is said to have been the first surgeon to remove both ovaries successfully at one operation. Many of the physicians of New York have a lively remembrance of the genial personal attributes of Dr. Atlee as revealed to them at a reception given in his honor by the late Dr. Marion Sims a few years ago, and his loss will be keenly felt by the profession of the whole country.

Richard McSherry, M. D., of Baltimore, Md., died at his home in that city on Wednesday, October 7th, at the age of sixty-nine years. He was born in Martinsburg, Va., received his early education at Georgetown College, and was graduated from the Medical Department of the University of Pennsylvania in 1841. He was immediately appointed to the medical corps of the army, and served under General Taylor in the Seminole War, resigning his commission in 1843. In the same year he was appointed an assistant surgeon in the navy, in which he served until 1851, when he resigned and settled in Baltimore. In 1862 he was appointed to the chair of Materia Medica in the Medical Department of the University of Maryland, and in 1865 to that of the Principles and Practice of Medicine in the same institution. He was a member of the Medico-Chirurgical Faculty of Maryland and of the Baltimore Academy of Medicine, of which he was one of the Founders and its first president. He was a writer of considerable repute, and the author of several medical works.

Letters to the Editor.

A NEW NATIONAL MEDICAL ASSOCIATION.

To the Editor of the New York Medical Journal:

SIR: As many are of the opinion that the usefulness of the American Medical Association is at an end, and that in all probability its future meetings will be characterized by acrimonious debates on medical polity to the detriment of its scientific interests, the time appears ripe for the organization of a new national medical association.

I would suggest, therefore, that it be organized in the following manner: Let each State medical society at its meeting in 1886 appoint two persons to represent it on a General Committee of Organization.

Early in 1887 this General Committee should be called together, the call for its meeting to be issued by the representatives earliest appointed acting as temporary chairman and secretary, and whose functions as chairman and secretary shall cease on the organization of the committee.

The duty of the General Committee shall be to prepare a plan for the permanent organization of the profession, the plan evolved by the General Committee to be submitted to the several State societies in 1888. If it should meet the approval of the majority of the State societies, the General Committee should issue a call for the general meeting of the National Association in 1889, which, when organized, terminates the labors and functions of the General Committee.

If the foregoing propositions appear to be open to serious objection, it is to be hoped that the objections will be formulated at an early day in order that they may be modified if generally thought desirable. It is further hoped that the medical press of the country will bring this matter before their constituencies with such commentary as seems to them wise.

Respectfully yours,

Subscriber.

COCAINE IN THE TREATMENT OF OPIUM ADDICTION.

314 State Street, Brooklyn,
Saturday, *September 26, 1885.*

To the Editor of the New York Medical Journal:

Sir: The able and valuable paper by Dr. Bauduy on "Cocaine in Melancholia," in your journal of to-day, contains a statement or two that we can not pass without comment and dissent.

Speaking of cocaine in the treatment of chronic alcohol- and opium taking, he says: "It not only replaces alcohol and morphine, but it generates a positive disgust for those agents. They can be withdrawn completely and at once without the slightest suffering or injury, and the cocaine itself may be gradually dispensed with, thus eventuating in perfect recovery."

This assertion as regards morphine is so at variance with my experience—based upon several years' exclusive professional attention to the treatment of opium habitués, and embracing case after case in which cocaine, in one-grain doses, subcutaneously, has again and again been given—that I am compelled to express my belief that Dr. Bauduy is *greatly mistaken.* His claim is entirely too sweeping, being, in effect, *specific* virtue for cocaine in opium addiction, which, I assert, it—or any other drug—does not possess. That coca—or its alkaloid—is of great value in this disorder I willingly admit, regarding it the most effective tonic-stimulant at command, but only as an *adjunct;* for opium addiction presents such *varied* reflex irritation on abrupt or rapid withdrawal of the habitual narcotic that its effective treatment can not be compassed by any *one* drug of which we know.

Such being my belief, it seems to me quite unwarrantable to assert that with cocaine a long-used opiate "can be withdrawn completely and at once without the slightest suffering." I do not believe it, and challenge proof to the contrary. It is too much like the asserted statement of Fleischl, that, with cocaine in the treatment of alcoholism and morphinism, inebriate asylums are a thing of the past—an assertion so astounding that it can be credited only to the vagaries of a visionary enthusiast.

Dr. B. cites *one* instance. A single swallow scarcely makes a summer. Let us have *cases* and details.

On another point our experience differs. He mentions a patient "for many years a hopeless victim." The morphine was at once withdrawn; one grain to one grain and a half of cocaine, hypodermically, given twice daily; craving for morphine immediately ceased, and all the usual sequelæ of withdrawal failed to appear.

No such remarkable result has ever followed my giving of cocaine, for invariably the effect has subsided in from two to three hours, my latest observation on this point having been made to-day. In this connection a paper on this topic by Dr. J. F. Whittaker, of Cincinnati, in the "Medical News" of August 8th, is of interest, his experience according with mine as to the transient effect of cocaine, and his opinion of its value being: "I am convinced that cocaine alone is not a perfect antidote or substitute for morphine."

Regarding the danger of a coca "habit," the opinions of these gentlemen are directly opposite, Dr. B. claiming it "a certainty," Dr. W. asserting "the fear of a cocaine 'habit' is quite ungrounded."

Personally, I think it possible, one such case having been under my care—a patient who used one pound of fluid extract of coca every two days. The gentleman recovered.

Dr. Bauduy's enthusiasm regarding cocaine may be the legitimate outcome of his experience with it in various disorders, but, in placing before the profession the conclusions he has reached, I respectfully submit that the one regarding its use in opium addiction belongs among those "not sufficiently matured by time and experience."

J. B. Mattison.

PUERPERAL DIPHTHERIA.

168 West Twenty-third Street, *September 30, 1885.*

To the Editor of the New York Medical Journal:

Sir: In your otherwise excellent report of my paper, read before the American Gynæcological Society, two errors have occurred, which you would oblige me by correcting—the more so as one of them might be of practical importance. "The patient complained of pain in the epigastrium" should read *The patient complained of pain in the hypogastric region.* The suppositories I have used contained a hundred grains of iodoform.

Yours truly,

H. J. Garrigues.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of October 1, 1885.

The President, Dr. A. Jacobi, in the Chair.

The President's Address was published in our last issue.

Obscure Cases of Weak Heart.—Dr. R. Van Santvoord read a paper on this subject, in which he said that weakness of the cardiac muscle, occurring independently of valvular lesion, was recognized as an important pathological factor in a large number of morbid conditions. It was a chief source of danger in acute febrile diseases; it occurred as a result of continued anæmia, and of alcoholism and other toxic conditions. Failing cardiac compensation was often the cause of death in chronic Bright's disease. The right ventricle was frequently affected in lung diseases which interfered with the pulmonary circulation. Degeneration of the cardiac muscle might result from inflammation in the course of general diseases, or as a result of lesions of the coronary vessels. Strain might weaken the heart. At the

autopsy there might be found granular, fatty, fibroid, or waxy degeneration. The heart structure might be found normal, although the history during life pointed to cardiac failure as the cause of death. In many of these conditions the diagnosis could easily be made, but in others the connection between the symptoms and the cardiac failure was obscure and liable to be overlooked.

Dr. Van Santvoord then proceeded to relate four histories of obscure cases of weak heart, and to study the significance of the symptoms which were present. The first case was that of a slightly corpulent man of forty-two years, who was apparently in robust health. He drank but little. Sleepiness was the symptom of which he complained—he fell asleep frequently during the day; and he was forgetful, and complained of headache. There was slight dyspnœa on ascending stairs. The only evidence of organic cardiac derangement was that the sounds, especially the first, were rather weak, and reduplication of the second sound was to be heard at the base of the heart. The symptoms dated back two years, when the patient had a severe attack of pneumonia. The diagnosis of weak heart following pneumonia was made. The treatment consisted in the administration of tincture of digitalis and tincture of nux vomica, the latter for indigestion. After two weeks the heart sounds became louder, but the patient was not apparently improved. Five grains of citrate of caffeine after meals were given in the place of digitalis, and one thirtieth of a grain of strychnine instead of nux vomica. The heart sounds soon became louder, and the disagreeable symptoms disappeared. When he was last seen, twenty-three weeks after the beginning of the treatment, the patient was in a comfortable condition, though slightly short of breath. There was persistence of reduplication of the second sound of the heart, heard at the end of inspiration and the beginning of expiration.

The second case was that of a stock-broker, aged thirty-eight years, who had had a number of slight attacks of gout, and several of whose relatives were gouty. He had been worried about business, and had drank freely. He had been short of breath; had had albumin in the urine; his ankles were puffy, especially after drinking brandy. He drank freely and ate little. One relative was asthmatic. The author had been called to him on account of dyspnœa and wheezing. He found the dyspnœa slight, the lungs normal; the first heart-sound weak, the second metallic and hard; not quite clear. The tongue was coated. He complained of flying pains in the muscles. The urine contained a small amount of albumin, and its specific gravity was 1·024. After six days' restraint from alcohol, administration of proper food, the use of morphine and Hoffman's anodyne at night, great improvement had taken place. The symptoms, however, returned when he began again to go about; the apex-beat was weak, the pulse was 102, and there were occasional pains shooting from the apex to the scapula. Digitalis and remedies for the condition of the bowels were administered, and within two days the pulse fell to 84, and its tension increased. He was restrained from alcohol, and after six months was greatly improved and in comfortable general condition. The first heart sound was still short and valvular, the second metallic and sharp, the arterial tension low, the pulse 82. The urine contained a small amount of albumin and many hyaline casts. In this case the abuse of alcohol and underfeeding had caused malnutrition of all the organs, but the rapid and continued improvement after the use of digitalis, especially in the cardiac action, was proof that the heart was the organ chiefly affected. The normal quantity of the urine, the small amount and inconstancy of the albumin, the absence of evidence of active kidney trouble, the low tension of the pulse, and the rapid improvement went to prove that the albuminuria was probably not associated with grave organic changes in the kidneys. The lesion in this case was conjectural; from the fact of the abuse of alcohol it might be inferred that there was fatty heart, but the rapid response to digitalis pointed to a less grave state of malnutrition. There was persistent irritability of the heart, due apparently to mental worry.

The third case was that of a man, aged fifty-four, who had been addicted to out-door sports. His health had always been good except for constipation. His illness began, some months before he consulted Dr. Van Santvoord, with lassitude, drowsiness, and distressing headache, chiefly at the vertex. He had for a long time been obliged to get up at night to urinate. Dr. Van Santvoord was consulted for an unusually severe attack of pain in the vertex and back of the head. The man was thin, sallow, and anxious; the tongue slightly coated; the appetite good. The apex of the heart was in the nipple line, in the sixth interspace, and at that point there was a faint systolic murmur. The cardiac sounds were weak. A mixture was given to correct the condition of the stomach, with the idea that the head symptoms were reflex, but no benefit followed. Faradization alone produced an effect upon the bowels. Ten minims of tincture of digitalis and twenty of tincture of chloride of iron were ordered, and during twelve days the heart sounds continued to increase markedly in force, the pulse became stronger, and the general condition improved very decidedly. The urine continued to be passed in large quantity; it contained no albumin or sugar; a few pus-globules were always present; its specific gravity ranged from 1·0105 to 1·0195. The patient had been treated for stricture, and had seminal emissions. From the enlarged heart and the great quantity of urine passed it was thought that he was suffering from contracted kidneys, with secondary heart failure, although the specific gravity of the urine was usually normal and it contained no albumin. The man went South, and remained in fair health. A year afterward he was a little short of breath, and had an indefinite disagreeable sensation in the head and occasional shooting pains in the arms and legs. The apex of the heart was in its former situation; the heart sounds, especially the second, were weak, with a reduplication of the first to the left of the sternum and on a level with the fourth rib. The sphygmographic tracing was of large amplitude, the tidal wave more marked, the aortic notch much higher in the tracing, and the dicrotic wave far less developed than in the case of the second patient. The pulse was 75. Digitalis and fluid extract of ergot caused, within ten days, diminution in the amplitude of the pulse, lessening of the dicrotic wave, and lowering of the pulse to 64. The sphygmographic tracing now differed from a normal tracing only in showing a little lower tension. The urine had a specific gravity of 1·015; it contained no albumin, and but few pus and red blood-globules. The fact that the patient had held his own for a year, the specific gravity of the urine being normal for the amount passed, and that the sphygmographic tracing showed low arterial tension, led to the conclusion that the polyuria was due to some other cause than contracted kidney, being possibly a reflex result of the urethral lesion. The cardiac failure, therefore, seemed to be an independent matter. The age of the patient pointed to an early stage of one of the chronic degenerative processes. His addiction to athletic sports suggested the weak dilated heart, without recognizable histological change, noticed by Münzinger.

The fourth case was mentioned only on account of certain special features. A boy, aged fourteen, had a severe attack of measles. His previous health had been good. After convalescence he suffered from dyspnœa and lancinating pain in the cardiac region on running. He was thin and pale; the cardiac beat was marked over the apex, in the epigastrium, and second left interspace, and both ventricular areas were enlarged. The

heart sounds were loud. There was distinct reduplication of the second sound in the third left interspace, near the sternum. A loud, blowing systolic murmur was heard over the arteries at the base of the neck, transmitted into the brachials and femorals. Improvement took place under the use of iron, strychnine, and rest; the dilatation of the heart diminished, the arterial murmur disappeared, and the venous hum became lessened, but the reduplication of the second sound persisted. The absence of cardiac murmur and the rapid improvement pointed to cardiac dilatation, with perhaps some fatty degeneration.

On reviewing the symptoms in these cases it would be seen that reduplication of one or other of the heart sounds was present in three of them. The cause of this phenomenon had been much discussed, but the simplest explanation was, that the reduplication of the first sound was due to asynchronism in the contraction of the ventricles, while that of the second was due to asynchronism in the closing of the aortic and pulmonary semilunar valves. Bramwell thought this the explanation in the majority of cases. Apart from purely theoretical speculations, which the author reviewed, it was a fact that persistent reduplication of the first sound had been found clinically associated with functional disorders and with grave organic changes of the heart, with or without valvular disease. It was at least within the limits of our present knowledge of the subject to say that its presence in a given case was presumptive evidence of cardiac lesion, the character and gravity of which would have to be determined by the other symptoms. As to reduplication of the second sound, it might be due either to derangement of the nerve apparatus or to lesions of the muscular fibers of the heart which caused the contraction of one ventricle to be a little shorter than that of the other, or to disturbances in the relative amount of resistance to be overcome by the respective ventricles. Aside from theory, as a matter of clinical observation, reduplicated second sound was so frequently associated with obstruction to the greater or lesser circulation, with lesions of the cardiac muscle, or with a combination of both, that its occurrence should lead to a careful study of the case with a view to determining the presence or absence of important cardiac disease. In the case of weak heart following pneumonia, the reduplication of the second sound was heard when last listened to only at the end of inspiration and the beginning of expiration—*i. e.*, it was of the normal type. The patient's condition at the time was comfortable, and an observer who knew nothing of his former history might wrongly have concluded that the sign was without significance. Regarding the weak first sound, in interpreting the meaning of a short, weak valvular first sound, it was obvious, from a study of the sphygmographic tracing in these cases, that the peripheral resistance to the circulation was quite as important a factor as the strength of the ventricular contractions. But in interpreting the meaning of a strong or a weak second sound we should consider not only arterial tension, but also the form of the ventricular contraction. The author felt convinced that closer observation and analysis of the less striking evidences of deranged cardiac action would greatly lessen the number of cases of grave cardiac lesion which remained totally unsuspected before an autopsical examination. Regarding the effect of digitalis and caffeine, it was plausible to suppose that the contrasted effect of the two remedies in the cases related might lie in the slighter influence of caffeine on the vasomotor apparatus. At any rate it would be seen that caffeine was sometimes efficient when digitalis failed. The greater safety and more rapid action of caffeine would make it preferable to digitalis in cases of heart failure occurring in acute diseases or primary degenerative processes of the cardiac muscle. The soluble and stable combinations of the alkaloid with salicylate or benzoate of sodium were preferable to the insoluble and unstable citrate. It should be given in divided doses, first small, and pushed as high as half a drachm daily.

The subject of the paper was discussed by Dr. John C. Peters, Dr. L. Weber, Dr. E. D. Hudson, Dr. A. H. Smith, and others.

PHILADELPHIA CLINICAL SOCIETY.

Meeting of September 25, 1885.

The President, Dr. Edward E. Montgomery, in the Chair.
Mary Willits, M. D., Reporting Secretary.

A Case of Empyema.—Dr. I. G. Heilman reported the case of E. M., aged nine years. His family history indicated some tendency to pulmonary disease, but his health had always been good. Dr. Heilman was called to see him on April 24, 1885, and found him suffering from an attack of measles. The case presented nothing unusual until April 29th, when pneumonia, limited to the lower lobe of the left lung, set in, and the case became more serious. May 1st he was hastily summoned, and found the patient suffering with intense pain in the left side of the chest, and exceedingly nervous. The symptoms suggested pleurisy, which the physical signs showed to be present. An opiate, with counter-irritants, afforded relief; but on the following day there was a decided effusion, which continued to increase in quantity until it filled the entire pleural cavity on the left side. Respiration being entirely suspended on that side, the dyspnœa was very great. The temperature varied between 102° and 103° F. The acute symptoms gradually abated, but there was very little decrease in the quantity of effusion. By May 13th, two weeks after the beginning of the attack, the patient seemed fairly comfortable, the temperature varying between the normal and 99·5° F. On measuring the chest the affected side was found to be one inch larger than the other. The percussion-note was still non-resonant; respiration sounds and movements were absent. Absorption seemed to have begun, when the patient's stomach became so irritable that scarcely any nourishment could be given for a week; the effusion again filled the left pleural cavity, and, in spite of quinine, potassium iodide, Basham's mixture, and hydragogue cathartics, with tincture of iodine and cantharidal collodion externally, the patient gradually grew worse. The temperature, however, during this period never rose above 100° F., nor the pulse above 95, except temporarily after exertion, or following an attack of nervousness. On June 19th Dr. E. R. Stone saw the case in consultation, and it was concluded that paracentesis was the only measure that promised relief. The condition of the patient at that time was not so serious as to cause the presence of pus to be suspected. His appetite was quite good; he spent a portion of each day on the street; he had fever only occasionally, and slept well. There was dyspnœa, but not to so marked a degree as would be expected in a case of that character. On June 23d an aspirating-needle was passed into the pleural cavity and eighteen ounces of pus were drawn off. No unpleasant symptoms attended the operation, and marked relief was afforded; the lung expanded, and twelve hours after a good respiratory murmur was found at the apex. The improvement was but temporary, and a week later the entire cavity had again filled. It was then decided to use the aspirator daily, and to remove as much of the fluid as the patient could bear. To obviate the necessity of a daily puncture with the needle it was decided to introduce a tube and to retain it in position. A puncture was made with an ordinary trocar and cannula, the trocar withdrawn, and a soft-rubber catheter was passed through the cannula, which was then drawn out over the catheter, thus leaving in the pleural cavity a tube to which the aspirator could be attached at any time. The catheter was held in position by a

strip of adhesive-plaster, and closed by a wooden plug. Aspiration was performed on nine successive days—June 30th to July 8th—and seventy ounces of pus were drawn off in all, which, with the first eighteen ounces, made a total of eighty-eight ounces. The aspiration of July 8th was followed by a little blood. From July 9th to July 14th a daily trial was made, but no further discharge took place. On July 11th a little water was injected, but was immediately forced out between the chest-wall and the tube. The lung in the mean time had expanded, and there was an almost normal respiratory murmur over nearly the entire chest, with good percussion resonance. On July 13th water was again injected, with the same result as before. On the 14th, in consultation with Dr. W. F. Buchanan, the tube was removed and the wound was closed with adhesive plaster. The left side at that time measured seven eighths of an inch less than the right side. The condition of the patient had decidedly improved; his appetite was very good and his strength was returning rapidly. He had since gained ten pounds in weight, had attended school, and taken part in out-door sports.

Dr. Heilman said that the points of interest in the case were: 1. The length of time (seven weeks) during which the lung was compressed until the aspirator was first used, in all eight weeks, before a regular systematic effort was made to remove the pus. Yet the lung steadily expanded as the pus was removed. 2. The time (nine days) required for the removal of the entire quantity of pus; there was no discharge after that time, and the tube might have been removed then with safety. 3. No antiseptic solution was injected—indeed, no attempt was made to wash out the pleural cavity. It was true that a small quantity of water, not more than two ounces, was injected twice, but that was done for the purpose of removing any clots that might have been obstructing the tube. He was aware that that was not in accord with modern teachings and practice, but it was difficult to see how antiseptic washings could have hastened the recovery of the patient. The aspirator in the treatment of those cases possessed, it seemed to him, so many advantages that he could scarcely conceive of a case where resort to the old method of open drainage would be justifiable. The simplicity of the operation in the one case and its difficulty and gravity in the other were points worthy of consideration. It was, he said, a trifling matter to puncture the chest-wall with a small trocar and cannula; but in a patient already exhausted it was often a most serious one to make two large openings and remove portions of the ribs.

Cleanliness was another point for consideration. In the case reported not a drop of pus escaped except when the aspirator was used. There was absolutely no unpleasant odor at any time, nor soiling of the patient's clothing—both so annoying when an open drainage-tube was used. A still greater advantage, in his opinion, was the control it gave the physician over the expansion of the lung, as he could cause it to expand rapidly or slowly, at his pleasure. The expansion being a gradual one, those distressing symptoms that so often resulted from a sudden removal of the fluid were avoided.

Dr. Heilman then exhibited the patient. The two sides of the chest resembled each other in contour; the percussion-note was the same on both sides, and a recent measurement showed that the left side was only one quarter of an inch smaller than the right.

Dr. Collins remarked that he noticed a slight friction-sound on the affected side, probably due to a deposit of lymph on the pleural membrane. He thought that if aspiration had been done earlier there would have been less danger of a deposit. He considered it an advantage to aspirate early, and would not hesitate to operate at the end of fourteen days. In regard to the use of antiseptics, he did not consider them necessary, as with the aspirator no air entered the pleural cavity.

Dr. Beates said that in his experience the entrance of air into the pleural cavity had caused no unpleasant symptoms.

Dr. Heilman, in closing the discussion, said that he had used the aspirator as soon as the consent of the parents could be obtained; they were very much averse to an operation. The pleural cavity was entirely filled, and there was some trouble in finding the intercostal spaces on that account. He thought that the escape of blood was due to the aspirator.

Tracheotomy in Croup and Diphtheria.—Dr. Edward E. Montgomery read a paper with this title. [It was reserved by the author for future publication.]

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of April 23, 1885.

The President, Dr. B. F. Westbrook, in the Chair;

Dr. A. H. P. Leuf, Secretary.

Aortic Stenosis and Regurgitation; Aneurysm of the Aortic Valves; Mitral Stenosis and Regurgitation.—Dr. Glentworth R. Butler read the following: "The patient from whom the accompanying specimen was taken was seventeen years of age, male, by occupation a tow-boy. He entered St. Mary's Hospital for the relief of an ulcer on the leg of two years' standing. He gave a history of acute rheumatism in 1878, and of constant exposure and insufficient nourishment. The ulcer was of traumatic origin, but healed promptly under proper treatment. After the stay of a month in the hospital he developed a lobular pneumonia from which he was fairly convalescent on April 1, 1885, when symptoms of cardiac distress led to an examination of the heart. According to his statement he had always been able to do a good day's work and had never had any symptom referable to a cardiac lesion. On examination, the apex-beat was found to be carried below and to the left of the nipple, with bulging of the præcordial space, and marked impulse in same region extending over a large area. On auscultation, a to-and-fro murmur was heard at the base over the aortic valves, and an apical systolic murmur, all three well marked. In addition, a faint presystolic murmur was detected over the area of mitral obstructive murmurs. A diagnosis was made of aortic and mitral obstruction and regurgitation with hypertrophy of the left ventricle. The after-progress of the case was rapid, dyspnœa and weakness increasing until death occurred on April 12, 1885. The lesions disclosed at the autopsy were as follows: The heart was greatly enlarged, and the increase in size was particularly in the left ventricle, which was dilated to at least twice its normal contents. The left auricle was greatly dilated and its walls thickened. The endocardium was thickened and opaque. The cusps of the aortic valve were also thickened and opaque. The posterior cusp was considerably stretched, forming an aneurysm. Large masses of vegetations were growing from all the cusps. There was a mass of vegetations on the wall of the ventricle one quarter of an inch below the aortic valves. The vela of the mitral valve were thickened and adherent, making a funnel-shaped contraction of the orifice. The tendinous cords were thickened and shortened. The papillary muscles were lengthened. The right side presented no marked changes, which is singular in view of the extensive lesions on the left side. The lungs were dark-colored at their bases, and showed patches of collapse, but no sign of an unresolved pneumonia."

Umbilical Hæmorrhage.—Dr. W. H. Thayer read a paper on this subject. [It will be published in full hereafter.]

Four Cases of Tait's Operation.—Dr. Joel W. Hyde read a paper with this title. [It will be published in full hereafter.]

Dr. L. F. Criado asked at what time with reference to menstruation the author operated.

Dr. Hyde replied that in the last case it was five days after the flow.

Dr. Criado had asked the question for one reason. He had seen many ovaries removed which he thought were not cystic, but contained only Graafian vesicles. He failed to see why these organs should be removed so much. He did not believe they all were cystic.

Dr. Hyde had intended to operate within a week after the cessation of the menses. As regarded cysts, in one case he could not see the ovary, but in its place a cyst of about the size of an orange. It contained at least a little more than a gill of fluid. In another case the ovary contained a cyst as large as a small walnut. Another had one which was about one third as large as the ovary itself. In all the cases there was sufficient disease of the oviducts to justify the operations, regardless of the condition of the ovaries.

Dr. Criado believed that extirpated ovaries were usually not much enlarged, at least so it appeared to him in those he had seen. He had doubts about many operations being justifiable. He had had two cases in which he had refused to operate, but in which it had been done by some one else. One of the ovaries he had been able to see, and it had seemed to him to be normal.

Dr. C. N. Dixon Jones asked if drainage-tubes had been used. He considered one necessary in Case III, and also thought that the microscope could easily settle the difference between a cyst and Graafian vesicle.

Dr. Hyde replied that he had already stated in the paper that no evidence of a recent peritonitis was discoverable, but that there were signs of an old peritonitis. The trouble seemed to be in the kidneys. Drainage-tubes were not used in any case.

The President said he believed that he could claim the honor of having done the first oöphorectomy in Brooklyn, in December, 1879. The patient was a domestic about twenty-eight years old. She had suffered from a gonorrhœa six years before. The uterus had evidently been inflamed, and remained hard, excessively tender, and with a contracted cervical canal and vagina. She suffered from the most terrible dysmenorrhœa, during the existence of which she frequently became comatose. All attempts to relieve her for five years had failed. Her health was broken, she was unable to work, and a constant cough caused considerable anxiety lest she should have phthisis. The menstrual intervals became prolonged to from two to five months. During one or two very severe attacks, accompanied by all the symptoms of dysmenorrhœa, but without the hæmorrhagic flow, there had been a slight discharge of blood from the rectum. The bladder was excessively irritable. She also had a lump of the size of an English walnut in the right mammary gland. The operation was performed with the idea of bringing on the menopause. He was assisted by Dr. George R. Fowler, Dr. F. W. Rockwell, and Professor E. S. Bunker. The operation was done under the carbolic-acid spray, and the wound closed with horse-hair sutures. On the second day she sat up in bed and pulled off her stockings, and on the third or fourth day she got out of bed, during the temporary absence of the nurse, and walked across the room to get a drink. By these proceedings she broke two or three of the stitches, but she made an excellent recovery nevertheless. Since the operation she had menstruated three or four times, at intervals of five or six months, and then the function had ceased. She had improved very slowly, but was now able to work, and had been in one place for fifteen months. At last accounts she was contemplating matrimony. It was interesting to note that the vesical trouble disappeared immediately after the operation, and that the mammary tumor also vanished. There were no peritoneal adhesions. The ovaries were of the natural size, but contained numbers of small cysts.

Complete Calcification of the Arch of the Aorta.—Dr. A. H. P. Leuf exhibited a thoracic aorta that was completely calcified from its origin at the aortic orifice of the heart to the opening in the diaphragm. Below the diaphragm it contained large calcareous patches. It had the appearance of an immense pipe, and was as solid as if composed of a shell of plaster of Paris and glue. He asked if any one present had seen a similar case?

The President recalled a similar case that had been presented to the society a few years ago, in which there was also complete calcification. It was presented by Dr. E. H. Bartley. The patient had died of inanition.

MEDICAL SOCIETY OF VIRGINIA.

Sixteenth Annual Meeting, held at Alleghany Springs, Tuesday, Wednesday, and Thursday, September 15, 16, and 17, 1885.

Dr. Bedford Brown in the Chair.

(*Continued from page 383.*)

Thursday's Proceedings.

Treatment of Lacerations of the Os and Cervix Uteri without Surgical Operation.—Dr. B. Brown, of Alexandria, read a paper with this title, and said that the value of Emmet's operation was acknowledged, although it was sometimes risky; but many women were so situated that they could never enjoy its benefits. Ten or twelve years' experience with some twenty cases had convinced Dr. Brown that these patients could be cured, without a surgical operation, by a simple, painless, safe, and easy plan of treatment which could be used by any practitioner. The nature of his cases had varied from trifling fissures to the most severe lacerations, and sterility had invariably coexisted. Many cases were complicated by cellulitis, localized peritonitis, subinvolution, metrorrhagia, displacements, proctitis, etc. In every case the general health was impaired. There were peculiar neuralgic pains in all those nerves coming within the circle of sympathy of the exposed and lacerated nerves of the os uteri. Thus, the great lumbar plexus manifested its sympathies in the form of constant aching pain in the base of the sacrum. Ovaralgia on the side of injury, or on both sides, if the injury was double, was almost invariable. In a few cases the development of sciatica indicated reflex sensation on the part of the sciatic nerves. Neuralgia of the crural nerves and their branches was common. These pains extended to the patella, and even down to the dorsum of the foot. Dr. Brown had healed several cases of laceration by first intention in the acute stage by means of absolute rest, disinfection, and cleanliness. If lacerations failed to unite immediately after labor by first intention, they never united spontaneously by second intention. Local treatment then became necessary. Dr. Brown always examined the womb, etc., for lacerations as soon as labor was completed; and, if found, he began, after the first twenty-four hours, a systematic course of treatment with a view to absolute disinfection and cleanliness. Warm douches of solutions of borax, boric acid, and carbolic acid were gently used two or three times daily, and the patient was kept in the recumbent position for two weeks. If healing did not occur by that time, it did not occur afterward spontaneously. Eight or ten weeks later, in such cases, he proceeded to procure union by the second intention. For this purpose he had used carbolic acid, chromic acid, Battey's solution of carbolic acid and

iodine, solid nitrate of silver, and even nitrate of mercury, but without favorable result. The nitrate of silver increased the inflammation, pain, and tendency to hæmorrhage. He then adopted graduated solutions of crystals of nitrate of silver with the best of results. Solution No. 1 was as follows:

℞ Argenti nitratis, cryst., ʒ ss.;
Aquæ destillat., f ʒ j. M.

This solution was to be applied to the interior of the cervical canal freely, down to the os internum, as the cervical canal was always involved in the rent and was left in a diseased condition. Solution No. 2 was:

℞ Argenti nitratis, cryst., ℈ ijss.;
Aquæ destillat., f ʒ j. M.

This solution was to be applied with a camel's-hair brush freely over the entire external surface of the os and cervix, including the fissure of the laceration, until a uniform white coating was formed, thick and tenacious, almost resembling a coat of paint. This gave immediate protection to the supersensitive extremities of the exposed nerves and tender granulations, and acted as a sedative application—allaying irritation, redness, inflammation, and engorgement rapidly, stimulating new vital action and healthy growth of granulations which filled up the fissures or cavities of the lacerations, and accomplished the healing of the wound by second intention. This coating, in the mean time, formed an impervious barrier to the further absorption of septic matter from the discharges, and in this way relieved pelvic cellulitis. The healing process and reduction of hypertrophy of the cervix and inflammation progressed rapidly. The process of absorption was stimulated in a wonderful manner, and the process of involution was also promoted in proportion. In simple fissure of the cervix, extending through the mucous membrane and fibrous tissue only partially, solution No. 1 should be applied thoroughly in the groove of the fissure, so as to reach its very bottom, and thus induce healing from the lowest depths of the wound; otherwise the object would be defeated. Solution No. 3 was:

℞ Argenti nitratis, cryst., ʒ jss.;
Aquæ destillat., f ʒ j. M.

This solution was only to be applied to the external surface of the cervix in the event hypertrophy and induration remained after the lacerations had healed; otherwise, if left in that condition, it formed a basis for the renewal of inflammation and re-opening of the wound. After treatment, the cervix became naturally soft and normal in dimensions. The os was not only not contracted by the application, but returned to a perfectly healthy condition. A great majority of females thus treated had since borne from one to three children, and had been entirely free from all uterine troubles. In three patients—one having borne three children, the second two, and the third one child after treatment for previous lacerations—the os uteri was found perfect as to softness, dimensions, and freedom from disease. Concealed fissures were often found after labor in the mucous membrane of the cervical canal, and caused an infinite amount of local disease, such as endocervicitis, hypertrophy of the adjacent tissues, inflammation of the fibrous tissues of the cervix, leucorrhœa, and often painful menstruation. A favorite locality for these fissures was at the internal os. The mucous membrane and submucous tissue were split through, and then the rent remained a source of trouble for years. The No. 1 solution of nitrate of silver reached these wounds admirably, and would surely heal them from the bottom.

Puerperal Septicæmia especially with regard to Prophylaxis and Ætiology.—Dr. George T. Harrison, of New York, read a paper with this title. Due credit was given to the labors of Semmelweiss for his valuable investigations, which pointed out the right road to the study of puerperal fever. He showed that childbed fever was a disease that came from without. Without a wound somewhere along the genital tract, puerperal septicæmia did not exist. After expulsion of the child and secundines in labor, the entire inner surface of the uterus was laid bare, like a part of the skin deprived of its epidermis by a blister. With this fact it was only necessary to call to mind the possibility of very rapid absorption of septic matters introduced into the vagina or the uterus. In primiparæ always, and in multiparæ generally, there were tears in the cervix, vagina, and vulva, and often lacerations or contusions of the perinæum. If a puerperal wound were protected from external influences it would heal like a wound on the surface of the body. But putrefactive organisms could develop in the living organism wherever dead tissues or fluids (as extravasated blood) were found, while the healthy physiological tissue in general opposed a considerable resistance to their multiplication. On the other hand, other pathogenous (disease-generating) micro-parasites find in the living tissues in the cells, in the blood, in the lymph-sinuses, etc., the favorable condition for development and multiplication. These fungi, endowed with specific powers, were entirely different from the putrefactive organisms, and were destroyed by the latter. In puerperal fever the carriers of infection were either the pathogenous fungi, which generated traumatic diphtheritis, pyæmia, and septicæmia, or they were putrefactive germs. The latter were ubiquitous; the former were imported, and got to the puerperal woman by the hands, instruments, cloths, etc., that might be used about the genitals. They were derived from suppurating surgical wounds, cadaveric poisons, and especially lochial discharges of women suffering with septic infection. A minimum quantity infected in the effective manner. The lochial discharges of puerperal sick during an epidemic were so infectious that they endangered life, by infection, of the non-puerperal woman to the pregnant, to physicians, and gynæcological cases where operations had been performed. In the puerperal woman the conditions for the rapid development of pathogenous fungi were most favorable. Contrary to general opinion, Gusserow had shown that there was no connection between puerperal sepsis and erysipelas, and that the micrococci of erysipelas could not produce pathological changes identical with septic processes. The pathogenous fungi affected the organism immediately, while putrefactive germs did so indirectly by their influence on decomposable matters, always present in puerperal women. An antogenous or autochthonous infection was an impossible thing. The characteristic features of non-pathogenous infection were (1) the late appearance of the fever, (2) the slight participation of the general condition, and (3) the existence of local morbid substrata. The principles of prophylactic treatment consisted in pure air for the lying-in woman, the careful avoidance of introduction of infectious matter into the genital passages, and the thorough disinfection of the genital tract. The physician's and the midwife's hands, instruments, etc., should be disinfected before using about a puerperal woman. Disinfection must be both mechanical and chemical. Use the finger-nail brush often, thoroughly washing the hands with soft soap, and then wash the hands again. Take off the coat and roll up shirt-sleeves. Then dip the hands and forearms in a disinfectant solution. Instruments and cloths should be dipped in about a five-per-cent. solution of carbolic acid for several minutes. During the pregnancy, especially if there be any puerperal-fever epidemic, the woman should frequently wash her external genitals with soap and water, and afterward with boric-acid solution. When labor set in, Dr. Thomas advised her to use a warm vaginal injection of antiseptic character, but Dr. Harrison protested against the injection under ordinary circumstances, as such injections were

unnecessary and fraught with danger. They removed the mucus which rendered the vagina soft and pliable, and most of the disinfectants used, especially carbolic acid and mercuric bichloride, coagulated the mucus and irritated the surface of the vagina. The bacteria naturally found in the vagina were not dangerous. But, if the patient had been subjected to the possibility of septic infection during the birth, then it would be eminently proper to use a copious antiseptic vaginal douche immediately after the birth and during the rest of the puerperal state. In tedious and complicated labors, where frequent examinations had to be made or instruments used, infections were absolutely indicated. Sometimes putrefactive decomposition of the uterine secretions occurred before labor ended. In such cases, complete the labor as speedily as possible, and thoroughly disinfect the genital tract by intra-uterine injections of carbolic acid or mercuric bichloride. Wash the external genitals three or four times daily, and disinfect once a day by carbolic acid or mercuric-chloride solution. Close all lacerations of the perinæum and vagina under strict antiseptic precautions, as by the continuous catgut suture. Iodoform dusted over the raw surface favored union. A powerful contraction and retraction of the uterus greatly helped in securing immunity from invasion of putrefactive bacteria; hence the value of Credé's method in expelling the placenta.

A Report on Advances in Surgery was read by Dr. H. Grey Latham, of Lynchburg, Va., who summarized the discussion last spring before the American Surgical Association on "The Field and Limitation of Operative Surgery of the Human Brain," disapproved of extirpation of the larynx and trachea, spoke favorably of drainage of the lungs for gangrene, etc., and said that laparotomies for many purposes were now established operations—such as for strictures of the intestines, strangulations, excisions of organs non-essential to life, etc. Do not wait too long, he said, in strangulations of the bowels; operate as soon as the diagnosis is established, as soon as vomiting sets in. Cut down so as to reach the cæcum. If this is distended, the obstruction is below; if it is collapsed or not tense, it is above. If the strangulated coil of bowel is gangrenous, resect it, and establish an artificial anus. When laparotomy is rejected, adopt Nélaton's enterotomy in the right iliac fossa. Dr. Latham laid down as propositions (1) that the best guide to the seat of an obstruction was not manual exploration, but visual examination, assisted, if necessary, by extrusion of the bowels, and (2) that no case of operation was properly concluded until an over-distended bowel was relieved of its contents. In operations for hernia, invagination had been laid aside or neglected, and obliteration of the sac or closing the neck was the popular procedure. Digital dilatation of the pylorus had been successfully performed for chronic non-malignant stricture. Through an incision into the stomach introduce a finger, and forcibly distend the stricture. In operative treatment for rectal cancer the following guides were said to be reliable: (1) If the finger can not be passed beyond the disease, unless it is confined to the posterior wall, do not operate. (2) The growth can be removed at a somewhat greater height when the disease is confined to the posterior wall. (3) If, when the finger has passed beyond the disease, the bowel is movable on the adjacent structures, generally speaking, the growth has not extended beyond the rectal walls, and the case is suitable for operation; but, if the bowel feels hard, rigid, and firmly bound to the surrounding organs, the case is unfavorable for an operation. (4) Examine carefully the abdominal viscera, and, if secondary deposits be suspected in the liver, no operation should be performed.

Advances in the Practice of Medicine.—The committee, through its chairman, Dr. Rives Tatum, of Harrisonburg, Va., reported some of the progress made in the healing art during the year. The subject of cholera, in view of its probable visitation to the United States next year, received due consideration. The comma bacillus was still *sub judice* as an ætiological factor, while its constant presence in all cases of genuine Asiatic cholera seemed to be admitted by all competent observers. Dr. Ferran, of Valencia, Spain, still practiced his system of inoculation to prevent cholera. His methods were pronounced by the various commissions engaged to investigate the matter as questionable, and the results as equally uncertain. In view of the fact that one attack of cholera did not prevent a subsequent attack, the principle of vaccination in this disease was likely to result in a failure. The new local anæsthetic, cocaine, had been found of signal service in the treatment of hay fever, used both locally and internally. The mercurial treatment of typhoid fever and diphtheria received due attention in the report, which claimed for the method a reduction of mortality in both diseases. The report claimed the unity of scrofula and tuberculosis, and called attention to peptones and mucin in the urine as interfering with tests for albumin. It alluded to the toxic alkaloids found in the body (ptomaines) as a possible cause of morbid processes, and closed by allusion to the new drug, antipyrin, giving a synopsis of its therapeutic indication and physiological action.

Clinical Notes on Carcinomatous Affections of the Digestive Organs; the Unreliability of Gastric Symptoms as Evidences of Gastric Pathology, was the title of a paper by Dr. R. C. Powell, of Alexandria, Va. He started off with a description of cancer, clinically considered, and reported several cases showing the obscurity of diagnosis. The cases illustrated two points of diagnostic importance: (1) Unreliability of gastric symptoms as evidence of gastric disease, and (2) the great value of cachexia as corroborative evidence of malignant disease. Dr. Powell regarded the cachexia as a more certain sign of cancer than the presence of a tumor. As to treatment, the indications were to sustain strength and to relieve pain. A judicious selection of food was necessary if the stomach be involved. Fatty, saccharine, and starchy foods were digestive chiefly in the intestines, and hence were best when the stomach was diseased. If the pancreas was the diseased organ, give meats, albuminoid substances, milk, etc., which were digested in the stomach; but all food should be pancreatinized before it was used. If the liver was the diseased organ, allow both meat and fish, but not salted nor highly seasoned. Salt-water fish were believed to be best. Fruit and vegetables—raw or cooked as preferred—were allowable. Permit "amusement without excitement, exercise without fatigue, and nutrition without stimulation." To relieve pain and procure sleep, use opium or morphia. Fowler's solution combined with bichloride of mercury; carbolic acid and tincture of iodine—one drop each—and bismuth subnitrate, were the commonly used medicines. When bismuth was combined with atropia, it was useful in the salivation of cancer. Cundurango and Chian turpentine had passed into oblivion, and alveloz would soon also be forgotten.

The Ætiology of Zymotic Diseases was the title of a paper by Dr. M. A. Kust, of Richmond, Va. He first reviewed the evolutionary history of the bacteria from their discovery by Leeuwenhoek, in 1682, to the present time. The germ theory was evolved from the fermentation theory—the morbid process of zymotic diseases being regarded as analogous to fermentation—the contagium playing the rôle of the leaven, exciting fermentation in the blood and humors of the body.

When Liebig appeared with his fascinating physico-chemical fermentation theory, his application of it to explain the morbid process of zymotic diseases was generally accepted, and for a long time his theory kept the yeast-plant—which, since its first

discovery by Leeuwenhoek, had been repeatedly discovered, forgotten, and re-discovered—in the background. When, finally, mainly through the efforts of Pasteur, the yeast-plant was universally recognized, the medical mind, dropping Liebig's theory, came to the conclusion that, if the active principle of fermentation was a living organism, the contagium of zymotic diseases must also be living matter.

Thus the germ theory was ready to spring into life; its way could never have been paved by practical medicine or clinical observations; the pathfinders were botanists, biologists, etc., who, by their researches and experimental studies concerning the ætiology of certain epidemic diseases among plants and insects, disclosed in every instance, as the incontrovertible primary cause of the disease, the action of some low form of life. Dr. Kust then gave a detailed description of the silk-worm plague and its stay by Pasteur. It now stood clear before the minds of the young medical generation that similar organisms must be found as the primary cause of the infectious diseases of mammalia—man included. And they were found at first, perhaps, in too great redundance for the credit of the theory.

Dr. Kust divided the microbes into three classes: Those which were undoubted, those of questionable character, and those whose existence was placed by induction and analogy almost beyond doubt.

The rapid progress made within the last decennium justified the hope that all remaining obscurities as to the relation between microbes and disease would soon be elucidated.

After this, however, there still remained three perplexing questions:

First, Whence came these numerous species of microbes?

The view hitherto entertained that miasms or germs were held in suspense by the air we inhale or by the water we drink was held by Dr. Kust to be fallacious. Any substance present in the air of a locality must have its source in the soil beneath or emanate from an object on the soil, whence it was continually renewed; and what the water contained in solution or suspension was also derived from the surrounding soil, or had found its way into it from without. The soil from the surface down to a considerable depth was the habitat of the bacteria, whence they arose in the form of the finest dust.

Not from the streets of our over-filled cities (provided they were broad enough to give free access to sunshine) arose this dust; it arose from the *soil* into our crowded, unventilated houses as the smoke from the hearth was drawn up into the chimney. No amount of sanitary measures hitherto devised would save a densely populated city from dying out in two or three generations (unless filled up by immigration) so long as the modern architect was allowed full sway.

Dr. Kust discussed the various views advanced concerning the transmutability of bacteria, the change from the specific into the non-specific form, and *vice versa*, and held that our present state of knowledge admitted neither affirmation nor denial.

The second question was, How does the morbid process of bacterial disease ever come to a happy end?

Since the development of the germ theory we had arrived at the perception that we had to reckon with two factors: the cellular-resisting power on the one hand, the degree of virulence and the numbers of the invading microbes on the other. The numbers were of the greatest importance. If a few microbes were sufficient to generate disease, what would happen to the doctors who were daily and hourly exposed to their onslaught?

Infection or immunity, abortive or fully-developed form of the disease, recovery or fatal end, were the resultants of the correlation between cellular-resisting power and the intensity and numerosity of the invading microbes.

But how should we physiologically conceive this cellular-resisting power? On this point we were still in the dark. A gleam of light was, however, dawning in the distance.

The white corpuscles, leucocytes, or migratory cells which circulated in the blood and were to be met with in every multicellular organism, constituting the blood of the white-blooded animals, and being present in the tissues of the lower animals which had no vascular system—these leucocytes, identical with the amœba found in all stagnant waters, had formed the object of the particular studies made by Dr. Metschnikoff, of Odessa. He could only make his experiments on animals (Bipinaria, Asteridæ, etc.) which were of such exquisite transparency that all occurrences within the living animal could be accurately observed from without. Just as one saw the amœba eating under the microscope, Metschnikoff could observe through the transparent teguments of those animals the leucocytes eat up all foreign bodies. It seemed that, by the division of labor in the multicellular organism, these leucocytes (which Metschnikoff had named phagocytes—eating-cells) had assumed the task of eating up all heterogeneous and waste matter, and eliminating what they could not digest.

The question now arose whether the phagocytes, if they ate up all foreign bodies, would not likewise eat up intrusive microbes?

The experiments hitherto made by Metschnikoff seemed to answer in the affirmative, and, should these experiments and observations prove conclusive, recovery or fatal end of the disease would depend on the proportion between the number of the phagocytes and the number of the microbes. The impenetrable mystery of the cellular-resisting power would have resolved itself into a prosaic, tangible eating power. The third question was, How was immunity effected through vaccination?

There were numbers of untenable, explanatory theories in the field. Instead of descanting upon them, as was his intention, Dr. Kust referred to the exhaustive criticism of these theories by Dr. Sternberg, U. S. Army, which appeared in the London "Lancet," June, 1885. In his explanation of immunity Dr. Sternberg rightly assigned the first rank to vital power, but the causative relation of vaccination to immunity still remained unexplained.

While Metschnikoff's eating-cells brought a solution, minds prone to speculation might, even at this early hour, be led to advance the following theory: That the first meal of microbes eaten by the phagocytes might prove so acceptable that in future they would always be ready to consume any reasonable number of the same kind of microbes that might present themselves; and this theory would rest on foundations possibly more solid than those of any other theory concerning vaccination as yet in the field.

(*To be concluded.*)

Miscellany.

The International Medical Congress.—The "Canada Medical and Surgical Journal" says:

"The new committee met in New York early last month and proceeded to do the best they could with the class of professional material at their disposal. The nominations of new presidents of the sections seem, in the majority of instances, most extraordinary. We are near enough to the States, and familiar enough with American literature, to know pretty well the names of the leaders in the different departments of medicine and surgery, but of the seventeen names of chairmen of sections there are twelve absolutely unknown to us as representatives

in their different departments. We ask of many, in blank astonishment, Who are they? What have they done? Where do they live? Truly the committee is sunk low when it must place such men at the head of important sections in an international gathering. The contrast between some of the past and present nominees would be simply ludicrous, were it not painful. The association is determined to have the Congress, and the remnant of distinguished men such as Flint, N. S. Davis, and Dalton, who have cast their fortunes with it, may do much to save it from being an absolute failure, but the leaders of the profession, and the workers who have made American medicine and surgery known here and in Europe, are not in it. The play will go on, but with Autolycus disguised as Hamlet."

When the foregoing was written, our contemporary was of course not aware that Dr. Dalton had declined to hold the position to which he had been nominated.

The "Canadian Practitioner" says:

"The new committee met in New York, September 3d, and made some concessions to public opinion, though not so many as we hoped to see. They amended the rule of membership so as to give representation to societies in special departments, and allow the so-called new-code men to become members of the Congress without the privileges of holding any offices. There was apparently no direct effort made to bring back the eminent men who have withdrawn from the organization. Until this is done it is hardly possible for the proceedings of the committee to command the respect and confidence of the medical world, which is looking on with fear and trembling.

"Among the most important acts of the last meeting was the election of Dr. N. S. Davis, of Chicago, to the office of Secretary-General. This will meet with general approval. The committee will get a fair support in New York, particularly from the Bellevue men. The name of Austin Flint, Sr., will be worth much among the shattered fragments that remain. Many able men in different parts of the Union will assist. We may derive what comfort we can from these considerations; but, after all, the broad, sad fact remains that the cream is principally gone, and we are left to feast on skimmed milk."

The Proposed New National Medical Association.—Commenting on the proposal to form a new national medical association in the United States, the "Canadian Practitioner" says: "It has been proposed to organize in the United States a medical association, corresponding to the Zurich Academy of Medicine, limited in numbers, and so honorable a body that membership in it would carry the highest reward that American physicians would have to hope for.

"The proposal, which is heartily indorsed by the 'New York Medical Journal,' has been made on account of the unpopularity of the American Medical Association. Its position has not been strong for years, but its recent action at New Orleans has capped the climax, and the consequence is that a strong feeling prevails that this association 'must go' if it be not thoroughly reorganized."

A New Physical Sign of Tricuspid Regurgitation.—Dr. W. Pasteur, of the Middlesex Hospital, London ("Lancet"), says: "In several cases in which there was reason to suspect functional incompetence of the tricuspid valve which have recently come under my observation, a physical sign has been present to which I believe attention has not been drawn, and of which I have been unable to find any mention either in the standard text-books or in the best known monographs on the subject of cardiac disease. This sign consists in a distension—with or without pulsation—of the superficial veins of the neck, occurring when firm pressure is exerted over the liver in the direction of the spinal column, and independent of the movements of respiration. A little consideration of the anatomical relations of the parts concerned will suggest the facility with which an impediment may be created to the flow of blood, in either direction, through the vena cava inferior by such a manœuvre, especially when the liver is obviously enlarged. It seems to me that the state thus produced is virtually that which obtains as a chronic condition in long-standing and severe cases of tricuspid incompetence as far as regards the tension in the systemic venous system in the immediate vicinity of the heart. Assuming the existence of tricuspid regurgitation and of a source of compression of the vena cava inferior, it is obvious that with each systole an excessive reflux of blood must take place into the vena cava superior and its tributary veins. It may be noted that the question of pulsation, as compared with distension or undulation, is merely one of degree of morbid venous tension. Although the number of cases in which I have observed this phenomenon is certainly limited, I have never failed to elicit it when there was indubitable evidence of tricuspid incompetence; on the other hand, I have hitherto invariably failed to obtain it in other forms of cardiac valvular disease, and in various cases of hepatic enlargement from causes other than passive congestion. I can not but think that this sign may furnish an important aid to diagnosis in cases where the usual signs of tricuspid regurgitation are ill-developed or in abeyance, and that it may prove a valuable factor in the difficult general problem of prognosis in cases of cardiac disease."

THERAPEUTICAL NOTES.

Baths of Permanganate of Potassium are recommended by Hüllmann, of Halle ("Arch. f. Kinderheilk."; "Dtsch. Med.-Ztg."), in the treatment of scrofulous affections of the skin, eczema, and intertrigo, and especially during the period of desquamation following measles, scarlet fever, and chicken-pox. For a general bath, 15 grains of the permanganate may be dissolved in a bucketful of water.

Pilocarpine in the Treatment of Stramonium Poisoning.—The "Medical Times and Gazette" states that a Hungarian physician, having been called to a child, four years old, in a comatose condition from having eaten, as her playfellows said, two handfuls of the ripe berries of the thorn apple (*Datura stramonium*), and in whose vomit the berries could be plainly detected, gave pilocarpine hypodermically, thinking that, as that had proved successful in atropine poisoning, it ought to be useful in datura poisoning also. He began with the fourteenth of a grain, and, as no effect was produced, he increased the dose to a seventh. As improvement was now evident, this was repeated. Altogether, in five hours he gave six sevenths of a grain, and by that time the child was convalescent. No physiological effects of pilocarpine were produced until the last dose was given, which was followed by profuse secretion of saliva and perspiration.

The Hypodermic Use of Osmic Acid.—Schapiro ("St. Petersb. med. Wchnschr."; "Med. Times and Gaz.") recommends the following solution:

Osmic acid	1 part;
Glycerin	40 parts;
Distilled water	60 "

He has injected this under the skin of the face without any untoward result.

Liquor Sodæ Chloratæ in the Treatment of Typhoid Fever.—Dr. Pearson, of Cape Colony ("Lancet"), believes that the duration of every case of typhoid fever may be shortened if it is taken in time. He gives notes of three cases in which he produced good effects with Labarraque's solution. To a lad fourteen years old he gave seven minims and a half every three hours, and to a girl of the same age tablespoonful doses of a mixture of a drachm and a half of the solution and six ounces of water.

The Administration of Nitro-glycerin in Angina Pectoris.—Dr. W. Murrell writes to the same journal, questioning the wisdom of the admission of only one preparation of nitro-glycerin into the new British Pharmacopœia—that of chocolate tablets containing one one hundredth of a grain each. Patients vary remarkably, he says, in their susceptibility to this peculiar remedy. One man takes the six hundredth of a grain, and suffers for hours afterward from intense headache, which incapacitates him for any kind of work; while another patient will take fifteen or twenty minims of the one-per-cent. solution ten or twelve times a day, not only without inconvenience, but with the greatest possible benefit. "The small-dose man would find his time pretty fully occupied if he had to divide each little tablet, weighing only two grains and a half, into six equal parts; while his large-dose colleague might experience some inconvenience in swallowing fifteen or twenty chocolate drops at a dose, especially if he were suddenly arrested by an anginal attack while crossing a busy thoroughfare." The alcoholic solution is free from the objection implied, is cheaper, and admits readily of the addition of adjuvants.

Lectures and Addresses.

RELIGION AND MEDICINE.

AN ADDRESS DELIVERED AT THE OPENING EXERCISES OF THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK, SEPTEMBER 29, 1885,

BY PROFESSOR WILLIAM MECKLENBURG POLK.

I WOULD give much to have the custom abolished which in our school demands each year an address from some member of the faculty. If we were allowed to discourse on a purely medical topic, one with which we should be familiar, the wish would be less pressing; but this we are forbidden by the unwritten law of this institution. Turn we must, then, to some other field for a subject.

Medicine is commonly thought to be a very exclusive pursuit, and yet, when we look about, it is a pleasure to realize how we mingle with those of other pursuits—how many are the points of contact between medicine and other objects of intellectual ambition. In the direction of either religion, law, or polite literature, we find fruitful fields of interesting inquiry; and each is so broad as to furnish material for a series of addresses. We will choose religion, and endeavor hastily to point out some of the matters of interest connected with its association with medicine.

From the very nature of its mission, medicine of necessity was the offspring of religion. One of the grandest, the most beneficent, unions between the two we find depicted in the records of the ancient civilization of Egypt. From the enlightenment which marked the priesthood of that country, they being in fact the center of the intellectual growth of ancient Egypt, it was to be expected that great results would accrue to medicine beneath their rule; and such was the case, for we find in their records evidences of a medical and surgical proficiency but little, if any, behind that of our middle ages. Three thousand years before the Christian era those men had formulated their precepts in a book which was to them a medical statute-book of such influence that, if its teachings were followed implicitly, the physician was held blameless, no matter what the result to the patient. Such was the dignity of medicine under these patrons, it wielded an important influence in the state, and much of the light which in our day has been thrown upon the life of that wonderful people comes from the medical writing of that period. There is good reason to believe that the temple of Serapis at Memphis was the center of ancient Egyptian medicine. There resided the fathers of the profession, the chief teachers, and there no doubt flocked all those who were afflicted with complex disorders, and no doubt it was there that the text MSS. and monographs were prepared. If such was the case, it was an admirable arrangement by which to sift the prolific and loose writing which perhaps afflicted the practitioner of that day. What a blessing some such institution would be to us! Could we have a central school to which the compositions of our contemporaries could be referred in order that all which was a stale repetition of accepted ideas might be suppressed, and all which was a real addition to facts might be recorded, what a saving of precious time would be gained to us—time now wasted in the perusal of old ideas in new dress which the ambitious but shallow enthusiast of our day insists upon laying before us!

In some instructive and pleasing books the Egyptologist Ebers, the scientific novelist, has spurred his imagination to present us with charming pictures of this union of religion and medicine, developing in one of his works the character Nebeuchari, an oculist, whose fame spreading widely over the East, was sought as the one to cure the blindness of the mother of the Persian King Cambyses, a feat which he accomplished by the operation of couching.

And yet it was through the work of this very king that a final separation of medicine from religion was brought about, for, as the conqueror of Egypt, he dealt its priesthood such a blow that, stripped of all prerogatives, they never regained their ascendancy in the state. Medicine after that was pursued as a separate profession. But truly it was a noble beginning for our calling to be thus fostered by religion as an ally in the most brilliant civilization of the early ancients—for it was a civilization that was full of wise and righteous conceptions; one that marked the birth of many other arts and sciences, which since have done so much for the happiness of our own era; one, too, that stands second to no other in the noble and enduring edifices with which it sought to manifest its devotion to its gods, vast temples adorned with massive pillars, approached through avenues of sphinxes and fronted by the obelisks (those graceful shafts of solid stone) which, bearing aloft their sacred inscriptions, were ornaments that imperial Rome and even our own fair centers of Christian civilization were but too eager to appropriate.

Turning to Buddhist India, that rival of ancient Egypt, we find medicine in a position far from favorable. In the hands of a special sect who were governed by oppressive laws, it was driven into an inferior position. But this was to be expected among a people whose religion was a grand system for the cultivation of selfishness. With them the end of life was "nonentity," the early attainment of which was devoutly to be desired. For, if it were not granted, the soul wandered from animal to animal, expiating in restless transmigrations the imperfections of the earthly life.

The attainment of nonentity or, as it was called, "Nirwana," being then the object of life, the devout should seek to destroy within himself all cleaving to existence, weaning himself from every earthly object, and, by a life of isolation —one given to self-denial, self-mortification—learn to sink into perfect quietude—apathy. This was the preparation for the end, a goal all the more rapidly reached as the preparation was the more perfect. In the face of such a religion, in the midst of the civilization that must spring from such a faith, a class could have but little place whose cardinal principle is that God has given man the earth and the fullness thereof for his enjoyment; whose aim is to free life from physical woe, to make it attractive by giving God's image the health with which to cultivate in vigorous, joyous strength the duties and obligations of this world; to pro-

long his days, that he may enjoy the fruits of his labors and correct the errors of his youth.

Coincident with the decline of Egyptian civilization began the rise of the Greek, and in nearly all essential particulars the one was based upon the other. This was distinctly the case with all that pertained to medicine. For, as in Egypt it began and was fostered as a part of the religious system, so in Greece the temples of Æsculapius were its places of abode; and as in Egypt the two were finally separated, so was it here. But the manner of the separation was different.

In Egypt it followed the crushing blow dealt the priesthood by the Persians; in Greece it resulted from the dawning of civilization upon the most active of the ancient minds —a mind which, drawing most of its best inspiration from Egypt, was quick to recognize that a time had come when the union of religion and medicine was no longer beneficial to either. The final blow to the dependence of medicine upon the religious orders was given by Hippocrates when he sought, though obscurely, to lay the foundation for its study as an inductive science, when he endeavored to apply to it the principle which about the same time Aristotle outlined as the inductive system of philosophy.

As Greek culture and thought overcame all intelligence to which they were opposed, so Greek medicine extended itself wherever Greek civilization obtained a footing. Thus it came about that, invigorated by that versatile people, medicine returned to the land of its birth, as a department in the Alexandrian Museum, and was in time to rescue from decadence the remnants of the art which yet resisted the decline which had fallen upon all purely Egyptian culture.

Unfortunately, it soon drifted from the anchorage which Hippocrates endeavored to secure for it, and followed the drift of the popular mind into the mazes of the speculative philosophies which, during the whole of the later Grecian and middle Roman periods, were the substitutes for religion with the cultured. This, as will be seen, was pregnant with dire results to medicine.

Such was the influence of one upon the other that we find many of the early philosophers making a special study of medicine or medical subjects as an aid to the development of their various systems.

Aristotle, the father of scientific research, the friend of Alexander, not only pursued it as an adjunct to his peculiar work, but found in one of its subdivisions a substantial means of support, for, after squandering an ample fortune, he gained his livelihood as proprietor of an apothecary shop at Athens.

It would be a pleasant task to follow medicine to the museum at Alexandria, that brilliant creation of Alexander's brother, and see what was attained under its direction, for surely much must have been accomplished under a system which even at the dawn of Christianity had invented the steam-engine. But our path leads in a different direction.

Looking next at medicine under the Roman Empire, we find it following the direction imparted by the Greeks, for, while their political system fell before the arms of Rome, their civilization remained triumphant and in turn overran the whole of Rome's vast empire. It will suffice to say that under the empire medicine in time received full recognition both in its study and in its practice. Its teachers, being provided for by the state, were associated with the teachers of rhetoric and other departments of polite learning, and of those who pursued it as a practice many held lucrative positions in the municipalities, and others attained high civil rank.

We now reach the most interesting part of our question —the relation of medicine to the Christian Church.

No one recognized the divine mission of our calling more clearly than the fathers of the early Church, and they were wise enough to avail themselves of it as one of the means of extending the faith. The religious medical enthusiasts who, under the name of Perabolani, penetrated most parts of the Roman Empire, in many places united the functions of priest and physician, by which device they gained freer access to the common people than would have been possible in the guise of mere propagandists of a new faith. While ministering to the body racked with pain, they could the more readily bring the troubled spirit to dwell upon the satisfying principles of the Christian faith, for the attitude of the sick pagan of that day was much the same as that of his ailing successor of to-day, the inclinations of both being illustrated in the familiar lines,

"The devil was sick, the devil a saint would be;
The devil was well, the devil a saint was he."

Apart from the aid thus derived from medicine as a means through which to reach the lower orders of society, there was much in common between the principles of a religion resting upon the divinely human precepts of the "Sermon on the Mount" and those of a profession whose purpose was the alleviation of human suffering.

Could those whose mission it was to guard, develop, and extend these principles have harmonized their interests, it would have been a happy day for medicine; but the exigencies of the occasion, the logic of events, drove them into antagonism.

We have seen the intimate relation existing between medical thought and culture and the pagan philosophies, an association dating from the time of Aristotle and finding its chief expression in the university at Alexandria, that center of pagan thought in the Roman Empire, and the most powerful opponent of the Christian faith.

This association had obtained for medicine not only full recognition in the schools, but great prestige before the people; it was but natural, then, that it should be arrayed on the side of paganism in the conflict which was waged between the pagan and the Christian. We can not wonder, then, that with the triumph of Christianity the intelligence and culture of medicine were swept aside, that its institutions of learning were suppressed, and that the regularly inducted members of the profession were almost supplanted by the Perabolani. It is true, however, that ample provision was made for replacing the pagan hospitals by others more in accord with the Church. Yet, noble as were these charities, they labored under an essential defect in having substituted for the educated, trained physicians, who had been the directors of such institutions under the old order, un-

skillful, though well-meaning and even enthusiastic ecclesiastics.

The consequences of this unfortunate and, for medicine, disastrous antagonism were seen in the gradually increasing credulity and imposture which in succeeding ages marked the practice of our profession. For at length it came to pass that there was an almost universal reliance on miraculous interventions, shrine and relic cures, as a means of healing the sick and maimed.

This method of pursuing medicine as a practical art reacted on its pursuit as a scientific study, checked its development, and tended to its debasement. But the faithful of that age have their representatives among us even now, save that now they are to be found only among the ignorant.

And, after all, the mistake committed by the fathers was that which all ages have witnessed—the blindness of man to the blessings God has already given him in the wonders of this creation if he will only have the wisdom and patience to put forth his mind and develop them.

While such was the fate of our science under the direction of the early ecclesiastics of the Christian Church, by one of those seeming inconsistencies which Providence sometimes displays in its workings, the Mohammedan faith was being illuminated through the influence of medical philosophy.

When first the children of the prophet overran the eastern and southern portions of the Roman Empire they scorned all learning not contained in the limited pages of the Koran. But through the influence of the Nestorians in Asia, and the Hebrews in Spain and Africa, these fanatics soon became enthusiastic admirers of learning. The manner in which this was brought about is a great tribute to the virility and universality of the principles of our profession.

The Mohammedan, the Hebrew, and the Nestorian found the pivot of their faith to be the same. All believed in the unity of God. But one of the party, however, accepted Mohammed as his prophet. Draper, in speaking of this, says: "No doubt estrangement on this point might have arisen, but a remarkable circumstance opened the way for a complete understanding between them. Both the Hebrews and the Nestorians had been among the most tenacious and successful devotees to the study of medicine, and the Hebrews especially had long produced distinguished physicians. These studies formed a neutral ground on which the three parties could unite in harmony, and so thoroughly did the Arabians affiliate with these their teachers that their physicians became their great philosophers, their medical colleges their centers of learning."

Medical philosophy, thus finding shelter with the Mohammedan and doing so much for their elevation and refinement, widening thus its influence, was naturally viewed by the Roman branch of the Church as even more offensive than when allied to the ancient philosophies; and when it became evident that Hebrew physicians, as exponents of Mohammedan civilization, were aiding in the development of barbaric western Europe, it is not a matter of wonder that that Church should have endeavored to degrade physicians as a class, teaching the people to regard them as atheistical disturbers of the divine order of things. And yet, while this was the general attitude of churchly influence toward medicine, some of the monastic orders were permitted to pursue its investigation; but these, as a rule, so cloaked it with the theories of the alchemist as to accomplish no more than the keeping alive an ill-directed spirit of fantastic inquiry.

By the thirteenth and fourteenth centuries Arabian medicine had made such inroads that the awakening spirit of Christian civilization began to avail itself of its enlightenment, and then we find numerous instances of a liberal patronage being extended to our profession by the great men of the Church.

And yet the ancient attitude toward medical culture—toward its pursuit as a department of science—had been too firmly imbedded to be easily uprooted; and even to this day, in spite of the upheavals of the Reformation, a remnant of that prejudice is witnessed in certain European countries in the social status accorded to the members of the profession.

But it is not disloyal in us to believe that, while the early Church felt constrained to antagonize medicine as a department of science, it was forced into the antagonism that it might all the more securely lay broad the foundations of that grand system of morals for the lack of which Egyptian, Greek, Roman, and Mohammedan civilizations, being weighed in the balance of human destiny, were found wanting; without which this glorious civilization of the nineteenth century could never have been attained. And in this era we can say that, in that she has given us this wonderful age, with all of its possibilities and achievements, she has fully compensated for every repression.

With that early Church the problems were indeed momentous, and the power with which she rose to the fulfillment of her mission was such as to draw from one of her keenest critics the following eloquent tribute:

"From her central seat at Rome her all-seeing eye, like that of Providence itself, could equally take in a hemisphere at a glance or examine the private life of an individual. Her boundless influence enveloped kings in their palaces, and relieved the beggar at the monastery gate. In all Europe there was not a man too obscure, too insignificant, or too desolate for her. Surrounded by her solemnities, every one received his name at her altar; her bells chimed at his marriage; her knell tolled at his funeral. She extorted from him the secrets of his life at her confessional, and punished his faults by her penances.

"In his hour of sickness her servants sought him out, teaching him by her exquisite litanies and prayers to place his reliance on God, strengthening him for the trials of life by the example of the holy and the just.

"Her prayers had an efficacy to give repose to the souls of his dead. When even to his friends his lifeless body had become an offense, in the name of God she received it into her consecrated ground, and under her shadow he rested until the great reckoning-day.

"From little better than a slave she raised his wife to be his equal, and, forbidding to have more than one, met her

recompense for those noble deeds in a firm friend at every fireside.

"Discountenancing all impure love, she put round that fireside the children of one mother, and made that mother little less than sacred in their eyes.

"In ages of lawlessness and rapine among people but a step above savages, she vindicated the inviolability of her precincts against the hand of power, and made her temples a refuge and sanctuary for the despairing and oppressed. Truly she *was* the shadow of a great Rock in many a weary land!"*

Original Communications.

GONORRHŒA IN THE FEMALE.†

By ANDREW F. CURRIER, M. D.,
NEW YORK.

A paper with this title was published by me in the "New York Medical Journal" for January 10 and 24, 1885, in which the hope was expressed that the attention of the profession in this country might be directed to this disease, which was believed to be much more frequent in its occurrence and important in its bearings than was usually supposed, even by well-informed members of the profession.

Various reasons have been given why this disease should be practically ignored by the body of the profession, and notably by the gynæcologists, within whose field its consideration would naturally occur. The principal ones alleged are the difficulties in its diagnosis and the poor results which attend its treatment. This is a humiliating confession when Sänger's statement is considered, that more than one ninth of all gynæcological cases are now believed to be of gonorrhœal origin. It seems additionally strange, also, when one considers the great prevalence of gonorrhœa in the male, and the attention which is devoted to its nature and treatment.

I trust I may be pardoned if I draw somewhat upon the paper to which I have referred; perhaps also some points in *this* paper, which may seem incomplete, will be found to be treated with greater thoroughness in the former one. The only claim which is made for this paper is that it is mainly a *résumé*, as faithful as possible, of the work which has been done in the investigation of this disease. The conclusions of the former paper, which subsequent experience and reflection have not induced me to modify, were:

1. Gonorrhœa in the female deserves more thorough investigation than it has yet received, especially in the light of recently established facts.

2. The diagnosis of the disease, with improved methods of investigation, chief among which are Sims's speculum and the microscope, is not so difficult as has hitherto been considered, even in the absence of direct information of actual exposure to gonorrhœal infection.

3. There is a difference between the characteristic discharge of true gonorrhœa, both as to its nature and its effects, and other mucoid discharges from the female genital tract. As a corollary to the foregoing statements, while investigators differ as to the significance of the micrococcus of gonorrhœa, its constant presence in the discharges is not denied.

4. Gonorrhœa in the female is identical with gonorrhœa in the male; the fact of individual peculiarities and susceptibilities is not questioned.

5. A series of careful investigations in well-defined cases, in a hospital or other place in which the changes and developments can be accurately noted, is desirable. No line of treatment can be recommended as unfailing and entirely satisfactory until the results of such investigations are known.

No important contribution to this subject has been made in American literature, in so far as I can ascertain, with the exception of Dr. Noeggerath's notable paper, which was read before the American Gynæcological Society in 1876, having been previously published at Bonn, in the German language, in 1872. It is but just to say that Dr. Noeggerath's views inaugurated an epoch in the history of this disease. They were received with great incredulity by the profession here and abroad. Their suggestiveness has borne fruit, however, in the experiments and observations of a number of careful workers, and some of those who were most outspoken in their disagreement with those views now give a more or less positive assent to them. Martineau and a few other French writers have recently described certain rare forms of the disease, but the most important recent contributions have been made within the past year in Germany by Bumm, Sänger, and Oppenheimer.

I.—In regard to the ætiology of the disease, while the evidence is not absolutely complete, even those who are skeptical will admit that the probabilities are altogether in favor of a parasitic origin. Such an origin was maintained by Neisser in 1879, after an elaborate series of investigations. Neisser was not the first, however, to assert such an origin, since Donné, in 1844, discovered a spore in urethral discharges which he named *Trichomonas vaginalis.*

Salisbury, in 1868, discovered *Crypta gonorrhoica;* Jousseaume, in 1872, discovered *Algue génitale*, and Hallier in the same year (1872) *Konotecium gonorrhoicum.* All these were forerunners of Neisser's gonococcus, but the latter was presented to the public at a time when the germ theory had captivated the minds of all men, and was therefore received with much more favor and sympathy than its predecessors. Bumm asserts ("Arch. f. Gyn.," xxiii, 3), as the result of extensive experiment, not only that the contagious property of this disease is located in the gonococcus, but that this microbe is distinguished from all others which are contained in the discharges from the genital tract by its faculty of penetrating living tissues and its manner of multiplication. Widmark has also shown ("Svenska läkaresällsk. Förh.," S. 159, 199, and "Jahrb. f. Kinderh.," xxiii, 1 and 2, p. 209) that in gonorrhœal conjunctivitis in adults the gonococci show the same tendency to penetrate below the epithelium of the cornea and into the lymphoid tissue which Bumm has observed in the tissues of the genital

* John W. Draper.

† Read before the Medical Society of the County of New York, September 28, 1885.

tract. In the cornea of the new-born infant, on the other hand, the lymphoid tissue is absent, and the gonococci are found upon the epithelium. The form and size of the gonococcus are stated by Bumm to be differential characters which are of minor importance, and these statements must be borne clearly in mind in examining the opinions of those who do not agree with Neisser and his followers as to the infective character of the gonococcus. The identity of this disease with the ophthalmo-blennorrhœa of new-born infants has been shown by Sattler, Haab, and other competent ophthalmologists, the distinction between it and ordinary purulent catarrh of the eyes in new-born infants consistiug in the absence of gonococci in the latter and their coustant presence in the former, from inoculation with gonorrhœal virus. (See Haab, "Rev. gén. d'ophthal.," June 30, 1885, p. 265.)

Of gynæcological investigators in this field, Kroner stated that, of ninety-two cases of ophthalmo-blennorrhœa neonatorum which he had seen, the gonococcus was found in sixty-three. (See "Am. Jour. of Obst.," February, 1885, p. 197.) He also examined the vaginal secretions of twenty-one mothers in the eyes of whose infants gonococci had been found, and of eighteen mothers in the eyes of whose infants no gonococci had been found. In the former group gonococci were found in all cases, and usually without the presence of any other bacteria. In the latter the characteristic hives of gonococci were absent, though diplococci were found. Nothing satisfactory could be obtained from the mothers in these cases respecting gonorrhœal infection, and the presence or absence of gonococci was taken as sufficient evidence for the basis of a diagnosis. Oppenheimer examined the secretions from the upper portion of the vagina which were taken from one hundred and eight pregnant women at the Heidelberg Obstetric Clinic, between January and September, 1883, and found gonococci in thirty of them (Untersuchuugen über den Gonococcus, "Arch. f. Gyn.," xxv, 1, p. 51).

He also made some investigations upon the subject of *ophthalmo-blennorrhœa neonatorum*, and found that it usually occurred within five days from birth, or about the usual incubation period of gonorrhœa, and that it was most frequent in those cases in which parturition had been tedious, notably in so-called *dry* births.

In cases in which blennorrhœa or corneal ulceration was present at birth, the supposition was advanced that the bacteria might have penetrated the fœtal envelopes and infected the *fœtus in utero*. As evidence of another character, Zweifel had the hardihood to inoculate the eyes of healthy infants with lochial secretions in which no gonococci could be found; no blennorrhœa resulted ("Arch. f. Gyn.," xxiii, 1883). Kroner also inoculated the conjunctivæ of five blind persons with secretions from the vagina of a pregnant woman in which no gonococci were found, no bad results following. In the case of another blind person the eyes were inoculated with muco-purulent matter from the vagina of a mother whose infant was suffering from simple purulent conjunctivitis, likewise with a negative result ("Am. Jour. of Obst.," February, 1885, p. 197). Important testimony as to the infective character of the gonococcus also resulted from some recent experiments of Welander ("Gaz. méd. de Paris," June 7, 1884, p. 267).

This investigator found gonococci in the purulent urethral secretions of seventy-nine women. In twenty-five of them he traced the source of the contagion, and discovered gonococci in the urethral discharges of each of the twenty-five men. Vaginal secretions which contained no gonococci gave negative results when used for inoculation purposes. This experiment was tried in three cases. In one the secretion was taken from the vagina of a woman who was menstruating at the time of the experiment. From the urethra of the same woman matter containing gonococci was also removed and applied to the healthy urethra of a man. At the end of two days this man began to suffer with an urethral discharge, in which cocci were discoverable upon the epithelial cells. On the following day there was a characteristic gonorrhœal discharge which contained an abundance of gonococci. Similar results followed inoculation with matter from the infective urethral discharges of the two other women.

Koch demands the satisfaction of three conditions in proving that a given infectious disease is caused by a given micro-organism:

1. That one and the same form of spore be always found in a given disease.

2. That the same be easily recognized, morphologically or by its chemical relations, as well as by its behavior to coloring materials.

3. That the disease may be artificially produced in a healthy individual by inoculation with pure cultivations of spores.

These requirements, says Oppenheimer ("Arch. f. Gyn.," xxv, 1, p. 51), are all fulfilled by Neisser's gonococcus in its relations to gonorrhœa. Pure cultivations have been obtained to the fourteenth generation, and, although the disease could not be induced (Oppenheimer, *loc. cit.*) in dogs, cats, puppies, and mice, it has been in the human subject by Bokai, Bockhardt, and Welander.*

Further testimony as to the infectious nature of the gonococcus is at hand, if it were required, from a number of observers who have treated the question experimentally. (See Leistikow, "Charité Annalen," 1882; Köningstein, "Arch. f. Kinderh.," 1882; Arning, "Vierteljahresschrift für Dermatologie," 1883; O. Haab, "Festschrift für Horner," 1880.) Among those who are still skeptical or incredulous with regard to the pathogenic powers of the gonococcus, mention may again be made (as in my former paper) of Sternberg. He maintains that the gonococcus is not morphologically distinct from all other bacteria ("Med. News," Philadelphia, xlv, 1884, p. 426), an identical one being found in normal human saliva, in pustules resulting from contact with the cadaver, and in the pus from acute abscesses; but he very properly adds that it is not essential for the gonococcus to have distinguishing morphological characteristics to establish its position as the cause of the infective virulence of gonorrhœal pus. This is simply in accord with what has already been quoted from Bumm's statements, and

* Stub reports that the gonococcus *will* produce a condition which closely resembles gonorrhœa, in all its details, in dogs and rabbits. "N. Y. Med. Jour.," May 23, 1885.

is also in line with Koch's cholera investigations, at least three bacilli having been discovered which present morphological peculiarities resembling those of the comma bacillus. In following these investigations, Sternberg and two other gentlemen applied to their own urethræ, August 23, 1884, cultivations of gonococci of the ninth generation, taking all necessary precautions that the microbes should not be disturbed. The results were negative, and these, with other similar unsuccessful experiments, tended to establish Sternberg's skepticism as to the infective properties of the gonococcus. He declares, however, with perfect frankness, that, notwithstanding his own failures, the experiments of Bockhardt and Welander, which I have quoted (See "Nord. med. Ark.," Stockholm, 1884, xvi, No. 2), together with evidence relating to other infectious diseases, warrant belief in the possibility that virulence does depend upon the presence of this micrococcus, which is a widely-distributed and usually harmless organism, but which may acquire specific pathogenic power, as a result of special conditions relating to its environment, which pathogenic power may be lost, he thinks, when these conditions are removed. This line of reasoning on the part of an expert and conscientious investigator seems, to my mind, a virtual admission of the special infective power of the gonococcus, especially when we bear in mind that there is no more inconstant quantity than the physical condition and susceptibilities of a given tissue of the body. Therefore the negative results of inoculation with the gonococcus, in any number of cases, need not outweigh positive testimony in a single case, if all the conditions are reliable. The immunity from contagious diseases in general which seems to be peculiar to some individuals is certainly no argument against the general theory of susceptibility to such diseases.

De Amicis professes ("France méd.," Paris, 1884, ii, p. 1095) to have produced blennorrhagia with injections of ammonia, and to have found micrococci and diplococci on the sixth day which he could not differentiate from those which were obtained in cases of urethritis with a clear history of contagion. He affirms that diplococci are to be differentiated from micrococci which are found apart from the genital passages only by their size, distribution, and mode of grouping. Bumm and Widmark have been quoted as insisting upon a more important distinction than this, namely, the property of penetrating living tissues. Neither De Amicis nor Sternberg has made any comment upon this characteristic. De Amicis agrees with Sternberg that the gonococcus may possibly have pathogenic properties under certain conditions, in which the mucous secretions act as cultivation-fluids. At such times the microbes develop with great activity, and may then possess an exceptional though not an original infective power. In legal medicine it was thought that the presence of gonococci could not be taken as a necessary evidence of venereal disease of inflammatory origin. Welander, whose important experiments have been quoted, concludes that there is a practical importance in the presence of these organisms, especially as a means of deciding upon the existence of infectiousness in prostitutes and others, which would certainly give them a value in a medico-legal sense.

Thus we have the arguments *pro* and *con* with regard to the infectious character of the gonococcus, and it appears that no one who has experimentally investigated the subject and whose work is accessible to the public ventures to give more than a modified dissent to the statements which were made by Neisser. That the microbe, at least in so far as morphological peculiarities are concerned, is not limited to the genital organs, or even to the eyes, is probable. Neither must it be overlooked that von Tischendorf professes to have found gonococci in the vaginal discharges of little girls suffering from scarlet fever, in which an origin by sexual contact was excluded, and in which, also, inoculation produced similar conditions in other children ("Am. Jour. of Obst.," Feb., 1885, p. 199), but, in this case also, there is no indication that the distinctive characteristic which was mentioned by Bumm was present. Little remains to be said regarding the ætiology of the disease. A history of recent impure sexual contact, in the presence of certain well-known clinical features, with or without an examination for gonococci with the microscope, will usually be accepted as sufficient evidence of gonorrhœa. The search for these microbes is always difficult, and often unavailing when only a few are present. That we are to depend mainly upon the clinical features for a diagnosis is agreed by Sänger, Fränkel, Kroner, and Noeggerath. This is especially true in many of the cases of latent gonorrhœa concerning which the skepticism of earlier days is passing away. The conversion of Fritsch, who was once one of the most pronounced opponents of Noeggerath's views, is an evidence of this.

(*To be concluded.*)

THE EARLY STAGES OF HUMAN DEVELOPMENT.

By CHARLES SEDGWICK MINOT, M.D.,
BOSTON.

(*Concluded from page 401.*)

The second specimen to be considered now is His's embryo L (1, Heft i, 135–139), which measured 2·4 mm. in length, and was obtained from a chorionic vesicle of 8 to 9 mm. diameter. The specimen had been considerably injured, and no exact knowledge could be obtained in regard to the heart or the disposition of the allantois or the amnion. Precisely these three points are elucidated by Coste, while His has worked out the internal anatomy of his specimen; in short, the two descriptions complement one another in a remarkable manner.

Nearly all that His ascertained is represented in the accompanying illustrations, Fig. 7. A gives a side view showing the thickening of the head end and the upward curving of the tail, and the two gill-slits in the cervical region; the mouth, *M*, is very large; between it and the first gill slit intervenes the thick ridge, *Mx*, of the first gill-arch (branchial or visceral arch, *auct.*), which becomes the mandible; between the two slits is the second or hyoidean arch, in connection with which the hyoid bone afterward arises. A large body-cavity is present, C, *Coe;* the walls of the body (somatopleures) pass over along an extended line into the amnion; the connection between the embryo and

the yolk-sack is already very much restricted compared with Coste's embryo, Fig. 4; at the side of the head a line and shadow mark the position of the optic vesicle. B is a ventral view; it shows the large, wide mouth, *M*, which, according to His, was apparently in communication with the intestinal canal, which is nothing but a straight tube with a great pharyngeal dilatation and a wide, open union with the yolk-sac; the median light band shown at the back of the mouth is the central nervous system shining through the covering tissue. C is intended to show the digestive tract, and is partly a horizontal section. Especially to be noticed is the enormous size of the pharynx (the region of the branchial arches), the straight, short intestine, and on each side of the latter the distinct body-cavity, *Coe;* there are indications of four visceral arches, *Mx*, *2*, *3*, and *4;* in front of the pharynx is shown the ventral surface of the fore-brain or first cerebral vesicle, with its lateral diverticula, the optic vesicles. D is a dorsal view of the brain and medullary canal, which is still open at *a*. The brain and spinal cord are already differentiated by the dilatation of the former. The brain subdivides very early in all vertebrate embryos into three dilatations or primary vesicles; but in this embryo the two anterior dilatations are not yet clearly separated from one another, hence there is only one widening of the brain in front; the front end is seen to bend downward and give off the conspicuous optic vesicles, *Op*, which therefore arise before there is any trace of the cerebral hemispheres—an important fact; the posterior and larger dilatation is the primitive medulla oblongata; no trace of the cerebellum has appeared. The whole nervous system is a tube the walls of which are of nearly uniform thickness, except that the dorsal wall of the third vesicle (the cavity of which becomes the fourth ventricle of the adult) is very thin. This thin wall is persistent in the adult and never develops into nervous substance. On each side of the medulla lies a round cyst, the auditory sack, *Au*, the beginning of the adult membranous labyrinth. Three other points not shown in the figures remain to be noticed. 1. In the tissue at the back of each body-cavity, *Coe*, was found a single longitudinal epithelial canal, the Wolffian duct, the first part of the uro-genital apparatus to be developed. 2. Close below the nervous system lay a median rod of cells with a small central cavity; this rod is the *notochord* or *chorda dorsalis*, the primitive embryonic axis around which the vertebræ are formed later. 3. All the tissues are still embryonic—that is, the cells are not yet differentiated into tissues. Unfortunately, the number and disposition of the myotomes were not ascertained.

It will be as well to mention here, rather than later, four descriptions of young embryos, which either belong in this stage or are a little older. Of these descriptions Remy's

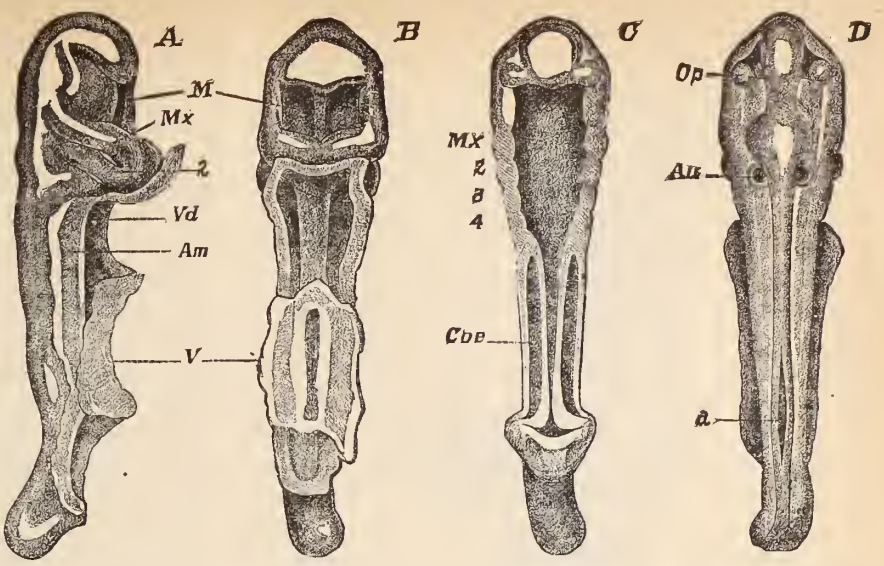


Fig. 7.—His's Embryo L; 2·4 mm. long. A, side view; B, ventral view; C, ventral view with the walls of the body and intestine seen in frontal section; D, dorsal view, showing the central nervous system. *M*, mouth; *Mx*, inferior maxilla or mandible; 2, hyoid arch; Vd, vorderdarm; *V*, splanchnopleure of the yolk-sack; 2, 3, and 4, gill-arches; *Coe*, cœlom or primitive body-cavity; *Op*, optic vesicle; *Au*, auditory vesicle (otocyst); *a*, point where the medullary groove has not yet closed.

alone brings much of any positive information, but the size and age of his embryo can only be guessed at.

The first of the embryos is Schröder van der Kolk's (5, p. 106 ff., with figures on Pl. ii). Kolk's figures are not very clear. He states that his specimen had two gill-clefts and measured 1·8 mm. in length; one can not but ask, Was it not really larger? Kolk's figure suggests that the specimen was doubled up; if this was the case, the embryo, when straightened out, would agree fairly well with His's embryo L, above described. Professor His, for reasons not clear to me, considers Kolk's specimen as somewhat older, but to this opinion I am unwilling to accede.

The second embryo is that of Hennig, whose description (6) leaves very much, and whose figures leave everything, to be desired. From this paper we can gather very little, except confirmation of Coste's statements in regard to (1) the disposition of the amnion and its connection with the stalk of the allantois; (2) the absence of a yolk-stalk.

Schwabe's (7) embryo, to which reference has already been made and which he assumes to be thirteen to fifteen days old, was probably sixteen to twenty days old, as shown both by his own data and by the description of the ovum. Very likely it was a little younger than Coste's embryo (*v. sup.*). There were a well-developed yolk-sac and an amnion closely investing the embryo, which was connected with the chorion by a short allantoic stem. The chorionic villi were considerably branched and entirely filled with mesoderm; their tips had little thickenings of the epithelium by which they were attached to the decidua; this was the only connection between the fœtal and maternal tissues. This last fact is an interesting confirmation of the observations of Ahlfeld and Langhaus.

Remy's embryo (8) was also a young one, but its exact age is not stated, nor are the measures of its length given, except in the title, where it is called "long d'un centimètre." From the stage of development, and from the statement in the text that the chorionic cavity measured 20 × 10 mm.,

it seems impossible that the embryo was so large; we should rather expect an embryo of 3 mm. Remy's figure is too inexact for one to make out the form of the embryo. If he gives the length correctly, the specimen must have been about a month old. As to its structure, Remy gives the following details: The medullary canal was still united with the ectoderm at its lower end, and extensively so over the fourth ventricle, which was entirely closed. The heart already had muscular striæ. The epidermis had two layers of cells, the outer somewhat flattened, the inner cuboidal. The cutis was not differentiated. The epithelium of the chorion he describes as maternal—a common error. He also distinguished the inner membrane of the chorion, the allantoic. He has also seen, apparently, what is known as Langhaus's cellular layer, but has taken it for a deep portion of the epithelium, which he accordingly calls many-layered. The cellular layer is a special stratum which arises between the connective tissue and the epithelium of the chorion; its origin is not definitely known. I am unwilling to hazard an opinion as to where Remy's embryo really belongs.

Summary.—During the fifth stage the head of the embryo acquires great prominence by the growth of the heart and the development of the branchial area. The chorion, of course, has enlarged, but we can not at present give its diameter exactly; normally it may be about 10 mm. The chorionic villi are constricted at the base and more or less branched; apparently they may either be hollow or may already contain a core of connective tissue. The allantois is still short and thick; the amnion is very much as in the previous stage, but of course somewhat expanded; the yolk-sac appears more like an appendage to the embryo. The embryo has enlarged, especially in front; its normal length we may assume to be about 2·6 mm., but this is very open to correction; the back is nearly straight; the thick caudal extremity curves upward; the heart and aortic arches develop rapidly, and accordingly is the region between the head and the anterior margin of the yolk-sac extended. The heart itself is still tubular, but makes a great bend to the right; the posterior end of the tube receives the veins, the anterior end forms a little enlargement, the commencing *bulbus aortæ*, and then gives rise to the aortic arches. Between the arches appear the gill-clefts at the side, and since there are five arches there are four gill-clefts. The pharynx, or region into which the gill-clefts open, is enormously dilated. The rest of the digestive tract is a simple tube communicating with the hollow yolk-sac. The Wolffian duct is present, but no other part of the uro-genital system. The notochord is tubular. The medullary canal closes throughout its whole length during this stage; it separates into brain and spinal cord; the brain consists of two dilatations, of which the anterior corresponds to both fore- and mid-brain, and gives off the long-stalked optic vesicles; the posterior dilatation is the hind-brain. The auditory organs exist as a pair of round otocysts.

6. EMBRYOS OF THE SIXTH STAGE. FORMATION OF THE HEAD BEND AND OF THE WOLFFIAN BODIES.

From this stage onward the embryo becomes more and more bent, the back becoming so convex that at one period the head and tail of the embryo almost touch. It thus becomes quite impracticable to measure the longitudinal axis, so we have to adapt ourselves to the circumstance and give as a measure for comparison the greatest length in a straight line of an embryo in its natural attitude. Formerly investigators usually attempted to give the actual length; consequently many of the older published measurements appear excessive in comparison with those now given; evidently this discrepancy is often only apparent.

The length of an embryo should always be given as obtained by measuring the greatest longitudinal diameter of the body, including the head; *the limbs ought* NOT *to be included*, because in the earlier stages, being at right angles to the body, they can not be included, and therefore ought to be excluded in the later stages in order to keep the measurements strictly comparable.

In the sixth stage (His's eighth) we find five aortic arches, the head bent down, the back convex, and the heart very asymmetrical. Our accurate knowledge of this stage in man we owe to His (Embryos M and BB). Besides these two, Professor His has also referred the following embryos described by other authors to this stage:

1. Allen Thomson's ovum, iii (2).
2. C. E. von Baer's, described in his "Entwickelungsgeschichte," Bd. ii, Taf. vi, Figs. 15, 16; also in von Siebold's "Journal für Geburtshülfe," 1834, xiv, 409.
3. Schroeder van der Kolk's (5).
4. Alexander Ecker's (9).
5. Professor Hecker's (*vide infra*).
6. Beigel's (*vide infra*).
7. Bruch's (10).

Of these, Thomson's embryo, the figure of which, reduced in scale, may be found in His (1, Heft ii, Fig. 18, marked AT 3 in the group of figures on p. 32), is the only one deserving much attention. Thomson's embryo resembles His's *M* (see below) quite closely, not only in general form, but also in the possession of two distinct gill-clefts and the great prominence of the heart. Its length is given by Thomson at $\frac{1}{8}$ inch—about 3 mm. Von Baer's embryo, on the contrary, was only 2 mm. long; it was surrounded by an amnion of about 4·5 mm. in diameter, which is abnormally large; von Baer observed four open gill-slits; the hind end of the body was partially atrophied, which accounts for the short length. Van der Kolk's embryo, as I have already stated, I refer not to this but to the previous stage—perhaps mistakenly, but I think not. In Ecker's ovum the chorion measured 12 by 9 mm., and the embryo only 2 mm.; the author's description is very meager and his figures are not distinct. Ecker expressly compares it with an ovum of Wagner's, figured in Wagner's "Icones Physiologicæ," and again in Ecker's "Icones Physiologicæ," Taf. xxv, Fig. 5; but the comparison apparently refers only to the chorion, for Wagner's embryo was evidently older, being 4·5 mm. long and having external traces of limbs. Hecker's ovum (1) I know only through Professor His's reference, which leaves the impression that Hecker's description is so unsatisfactory as to render it a matter of surmise exactly what stage of development the specimen had reached. In regard to Beigel's ovum (in the previous article I ex-

pressed my opinion that it is a much older and abnormal embryo) I do not differ with Professor His as to the slight value attaching to Beigel's description. Bruch's embryo (10, Bd. vi, Taf. x [40]) appears to me, from his description and plate, to have been very abnormal.

Of these seven embryos, Van der Kolk's and Beigel's do not belong to this stage; von Baer's and Bruch's were abnormal; Hecker's is questionable; Ecker's is somewhat uncertain; and Thomson's is the only satisfactory one. Of Thomson's only the general appearance is described, but that confirms what we learn from His's two embryos, M (1, Heft i, 116–134) and BB (1, Heft ii, p. 90, and "Arch. f. Anat. u. Physiol.," anat. Abth., 1881, pp. 310, 311). The latter embryo has also been catalogued by His with No. lxv.

M appears to be somewhat the younger, but no data as to its age are preserved; the embryo was 2·6 mm. long, its chorion 7·5 × 8 mm. in diameter. The embryo BB was 3·2 mm. long; its chorion 11 × 14 mm. in diameter; its age, from the data given by His, I think was probably twenty to twenty-one days. The following description refers to M only, as the full account of BB is not yet published:

The head is bent down, the back is very convex, and the caudal extremity is rolled up and turned toward the right, while the head is twisted slightly toward the left; the long axis of the body therefore describes a large segment of a spiral revolution; the spiral form is more marked in embryos a little older; it is, of course, produced by the more rapid growth of one side; in view of the differences between right and left in the adult, it is very interesting to find differences between symmetrical parts showing so very early in the heart of the embryo and the twisting of the body. The caudal end of the body has grown very much; the allantois-stalk has presumably lengthened; the neck of the yolk-sac is much constricted; four gill-arches can be distinguished externally; the otocyst, Fig. 9, *Ot*, has become somewhat pear-shaped. The neural canal is completely closed, the mid-brain and fore-brain have become perfectly distinct, and the latter has begun to form the hemispheres in front. The mouth is large, and at its upper corner the protuberance of the maxillary process is marked; the mandibular process is very prominent.

Fig. 8, a geometrical reconstruction from the sections, shows the anatomy of the entodermic canal. The pharynx, bounded on each side by five branchial arches, is still very large and tapers down posteriorly; the intestine is turned to the left and opens into the broad canal, *V*, of the yolk-sac; just in front of the yolk-sac there is a small ventral diverticulum, *Li*, probably the commencement of the liver; behind the yolk-sac the cylindrical intestine runs over into the tail, where it expands into the cloaca and gives off a cylindrical canal, which has very thick connective-tissue walls, and is the allantois-stalk, *All.* This is the youngest allantois of which the structure is known; therefore we add at once that the walls carry two large allantoic arteries, Fig. 9. The body-cavity, Fig. 8, *Coe*, has at its back on each side a longitudinal ridge, the commencement of the Wolffian body; the ridge already contains traces of the canals of the Wolffian body.

Of special interest is the arrangement of the circulatory apparatus, Fig. 9, since this is the youngest human embryo of which the vascular system has been elucidated. To

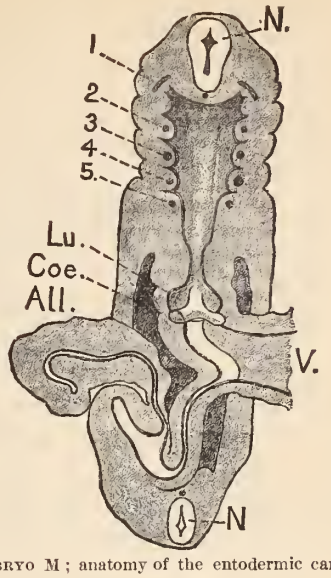

Fig. 8.—His's Embryo M; anatomy of the entodermic canal. *N*, *N*, central nervous system; 1, 2, 3, 4, and 5, gill-arches; *Lu*, liver; *Cœ*, body-cavity; *All*, allantois; *V*, stalk of yolk-sac.

avoid confusion, it must be stated that the whole of the aortic portion of the heart up to the origin of the aortic

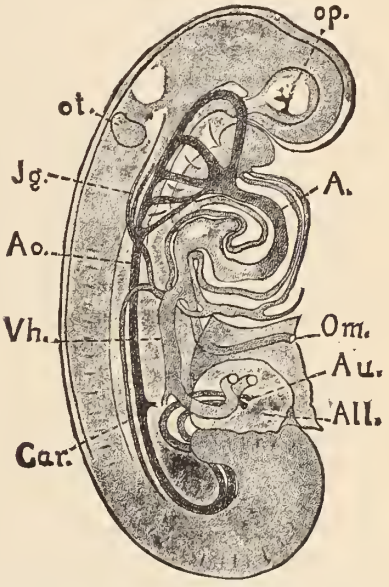

Fig. 9.—W. His's Embryo M. *Op*, optic vesicle; A, aorta; *Om*, omphalo-mesaraic vein; *Au*, arteriæ umbilicales; *All*, allantois; *Cars*, cardinal veins; *Vh*, right umbilical vein; *Ao*, dorsal aorta; *Jg*, jugular vein; *ot*, otocyst.

arches is double-walled, there being a very considerable space between the endothelial tube and the main mesodermic wall. In the figure the arteries are shaded dark. The heart is an S-shaped tube; the venous end is convex toward the head, the arterial end convex toward the tail; when viewed from in front, the venous portion is seen on the left, the arterial portion on the right of the embryo. The heart is continued forward by the large aorta, *A*, which gives off five branches on each side of the neck; these branches unite again on the dorsal side and run backward, to unite with the fellow-stem and so form the single median dorsal

aorta, *Ao*, which runs way back and terminates in two large branches, *Au*, which, curving round, pass out through the allantois-stalk. The five branches in the neck are known as the aortic arches, and the column of tissue around each branch constitutes a so-called branchial or visceral arch; between the five arches are four spaces, in each of which a gill-cleft is ultimately formed. The veins are: 1. The jugular, *Jg*, and cardinal, *Car*, which unite and form a single transverse stem, the ductus Cuvieri; the cardinal veins receive chiefly the blood from the Wolffian bodies, and atrophy later with the bodies. 2. The large umbilical veins which pass up, *Vh*, from the allantois and also open into the ducti Cuvieri, but nearer the heart than the jugulars and cardinals. 3. The omphalo-mesaraic veins, *Om*, which come up from the yolk-sac.

His describes for both embryos the disposition of the pericardial cavity and the septum dividing it from the body-cavity with great minuteness, in order to elucidate the development of the diaphragm. But this problem is so obscure and complex that it is best not to touch upon it here.

Summary.—During the sixth stage the most striking changes are the curling up of the embryo, the closeness of the amnion to the embryo, the contraction of the neck of the yolk-sac, the growth of the caudal extremity, the assumption of the pear-shape by the otocyst; internally, by far the most important advance is the appearance of the Wolffian bodies.

The embryo is from 2·6 to 3·2 mm. long and about three weeks (twenty-one days) old; the chorion is from (say) 8 to 13 mm. in diameter. Besides the points noted above, we may mention for this stage the separation of mid- and fore-brain, the commencement of the hemispheres, the progress of the vascular system, especially in the heart, which has distinct auricles and ventricles, also the bending of the intestinal canal into an unsymmetrical position.

APPENDIX.

1. *Contents of the Chorionic Vesicle.*—In early stages, as we have seen, there is a large chorionic cavity, which in later stages is obliterated by the expansion of the amnion. The space between the chorion on the one hand and the amnion and the yolk-sac on the other is filled with a fluid which is coagulated by the action of hardening agents, making a network of threads. This observation, which has been often verified, is all that we know concerning the nature of the chorionic fluid; it is probably of a serous character, and may very likely be found to contain free connective-tissue cells (wandering cells or leucocytes).

2. *Structure of the Yolk-Sac.*—The histology of the yolk-sac has never been properly studied. In regard to its structure in earlier stages I can find no observations. Kölliker ("Grundriss," 162) states that in the fourth or fifth month it is from 7 to 11 mm. in diameter and hollow, with an external envelope of connective tissue and an internal pavement epithelium of fatty cells. The inner surface has small vascular villi, rudimentary remains of structures said to be well developed in some of the lower vertebrates.

In regard to the contents of the yolk-sac, von Baer states (12, ii, 272) that in very young ova (six to seven weeks) the contents are sometimes as thick and yellow as the yolk of a bird's egg; in ova of this period the thinner the contents the more rounded and fully distended is the yolk-sac. A little later the contents are always fluid, but at the end of pregnancy, according to B. S. Schultze (11), when the sac has shrunk to 4 to 7 mm. in diameter, it contains variable quantities of fatty substances and carbonates. It thus appears that during the first month at least the yolk-sac does contain more or less true yolk—an idea which is confirmed by Rauber's observations on the rabbit's ovum. It seems, indeed, probable that the rudimentary yolk-sac of man still performs for a short period the function of a food reservoir for the embryo.

FOUR CASES OF TAIT'S OPERATION.*

By JOEL W. HYDE, M. D.,

CONSULTING GYNÆCOLOGIST AND OBSTETRICIAN TO LONG ISLAND COLLEGE HOSPITAL; CHIEF TO THE DEPARTMENT OF OBSTETRICS, ST. MARY'S HOSPITAL, BROOKLYN; MEMBER OF KINGS COUNTY MEDICAL SOCIETY, AND MEMBER OF THE BROOKLYN PATHOLOGICAL SOCIETY.

Tait's operation for the removal of the diseased uterine appendages has, during the last decade, passed through all the stages of criticism by the profession, from that of astonishment at its boldness and denunciation of the use of so radical a treatment, to that of an almost universal acknowledgment of its value.

There are still, however, a few medical men who shake their heads and repeat the old threadbare arguments against this operation which have been answered a hundred times over, and, at last, with statistics so overwhelmingly convincing, both as to the safety of the operation and its satisfactory results, that few now deny it its proper place in surgical history and science.

Battey first operated in this country (1872) for the removal of diseased ovaries. His operations failed more frequently of good results than those of the present day, as he found that menstruation often continued uninterrupted. To hold this function in abeyance was, moreover, the great desideratum.

Tait afterward announced his belief that the Fallopian tubes were an important factor in menstruation, and that they should also be removed in order to bring about the menopause more rapidly; furthermore, this was necessary, as the tubes were as likely as the ovaries to be the seat of the disease sought to be remedied by the operation.

From this came the name of "Tait's operation"; and he certainly has the honor of having performed it a greater number of times, and with less resulting mortality, than any other living surgeon.

I have reported these cases for two reasons: 1. Because the ætiology is, I believe, unique in at least two of them—one being of malarial, and another of scarlatinal origin. 2. In an operation of so recent adoption and of such gravity, the most accurate statistics of all cases should be preserved for future use.

I have, furthermore, purposely delayed this report for several months that I might be able to give, not only the history of the operations, but also the subsequent condition of the patients.

Case I.—Mrs. M. M., American, aged twenty-nine, married nine years. Menstruated first at about fourteen years of age. Menses normal, except that they were profuse. At seventeen she began to suffer much from dysmenorrhœa, and her flow was menorrhagic; still later it became metrorrhagic, it often being difficult to define the beginning or ending of a period.

At eighteen she had an attack of peritonitis, which was so severe as to compel quietude in her room for months.

Subsequently her general health improved somewhat, and she married. Her periods of intense suffering soon reappeared, however; her menstruation was more irregular, and the pain unfitted her for her ordinary household duties. Hystero-epileptic attacks became frequent, followed by melancholia, at which times she exhibited a suicidal intent, and was three times prevented from taking her life by the watchfulness of friends.

I first saw Mrs. M. in June, 1883, and had her under care for three or four months. Treatment availed nothing except to mitigate her sufferings temporarily and disclose fully the nature of her disease, which was diagnosticated as chronic ovaritis of both sides, with salpingitis of the left side.

Tait's operation was finally advised, and readily acceded to by both patient and friends, as the only hope of future relief.

Operation, November 11, 1883.—An incision of two inches and a half was made in the median line, just above the pubes, and the abdominal cavity opened. The peritonitic adhesions were found to be so dense in every direction—all the viscera being matted together—that it required the most patient dissection with fingers, knife-handle, and scissors, before the fundus uteri could be reached; this was found bound down with the Fallopian tubes so firmly that it was necessary to increase the abdominal opening sufficiently to pass in the whole hand, to reach and tear the ovary from its bed of strong adhesions. This accomplished, the tube was transfixed as closely as possible to the uterus with a double silk carbolized ligature, one half tied on each side, and the left ovary and tube removed. The right ovary and tube were then sought and removed by the same tedious process, and presented much the same appearance, except that the cysts in the left ovary were larger than in the right. The stumps were thoroughly seared with the galvano-cautery. The left Fallopian tube was only a little over an inch in length, much distended, and gave every evidence of the correctness of the diagnosis of salpingitis. The right tube was about two inches and a half long, with some dropsical distension near inner third. The wound and cavity were now carefully cleansed with a two-per-cent. carbolized solution, great care being taken to guard against any points of oozing, after which the abdominal wound was brought together with nine deep silver sutures and silk superficial sutures. The dressings used were Am Ende's—naphthalinated dressings of cotton, cotton gauze, and jute, completed with a flannel binder. Sickness at the stomach was relieved by small quantities of hot water sipped, and pain allayed by opium, large quantities of which were used owing to her previous opium habit. This habit she had entirely conquered by the third week, and has not resorted to it since. The sutures were all removed by the tenth day. Her temperature never rose above 100·75° F., and her convalescence was prompt.

She has recovered all her former cheerfulness of manner, and, while not a robust person, is able to perform the duties of her household with a fair modicum of comfort.

She still continues to menstruate, now eighteen months after the operation; but her periods, which, after the operation, were at first five days, have gradually grown to be

* Read before the Brooklyn Pathological Society, April 23, 1885.

about one day in duration, and a greater lapse of time between them.

Case II.—L. J., American, aged twenty-seven, unmarried. Menstruated first at sixteen, always irregularly and profusely. Of late years she has suffered intensely with dysmenorrhœa, headache, loss of appetite, and especially with pain in the region of the sacral plexus. This pain has been of that character that she has been unable to lie on her back for several years, and what little sleep she obtained was in the genu-pectoral position with pillows stuffed up hard against her abdomen. She was treated for two years for spinal trouble by a specialist in New York, but I have never seen any evidences of such a difficulty. There is a very pronounced asymmetry of her body, but I learn from her mother that it has existed from her infancy. The mammary gland, the thigh, and leg of the left side were very much smaller than the corresponding parts on the right side; in fact, the whole muscular structure of the left side presented an appearance of atrophy.

There were great tenderness and pain over both iliac regions for the greater portion of the time, a general weariness and inability to do much or enjoy anything. She also had much mental depression and a desire to resort to extreme measures for relief. Examination revealed an enlarged and very tender right ovary, with a prolapsed left ovary; both tubal tracts very sensitive. Tait's operation advised and performed November 19, 1883, at Long Island College Hospital. There were no adhesions except a few which bound down the left ovary in its prolapsed situation behind the uterus, and which were readily separated; this ovary was considerably less than normal in size. Whether its small size was a part of the general asymmetry, previously mentioned as existing in this case, is difficult to decide, but I believe it to have been so. The right ovary was enlarged and distinctly cystic, one small cyst being ruptured while attempting to remove it. Both tubes were ligated as closely as possible to the uterus with carbolized catgut, seared with the cautery, and dropped back into the abdominal cavity. The same kind of sutures and dressing were used as in the previous case. She was placed back in bed in forty minutes, and, aside from some cystitis which developed the second week after the operation, convalesced rapidly.

She left the hospital November 30th, traveling by rail quite a distance to her country home.

Case III.—Mrs. G., aged thirty-five years; married; sterile; was always healthy and robust till seventeen years of age, when she had an attack of intermittent fever of great severity, the effects of which lasted two or three years. Following this she began to suffer with dysmenorrhœa, which every year increased in intensity, and which later on was complicated with evident attacks of localized peritonitis, both pelvic and abdominal. There was some constriction of the vagina, and small bands of adhesion ran between the cervix and upper vaginal walls on either side. Coitus was intolerable; and the most careful digital examination produced nausea and fainting, compelling her to keep her bed for that day. As far as it was possible to learn from an examination, there was great tenderness of the left ovary; the right ovary was undetected, but an undefined and fluctuating mass filled up that region of the pelvis, which was supposed to be a cystic ovary. There was much less mobility of the uterus than usual. Tait's operation advised and performed at Long Island College Hospital, January 22, 1884. This operation was similar to the first in the vast adhesions everywhere encountered, and which rendered the whole work, from the first incision to the final touch, a blind and difficult dissection. The left ovary was first sought and found imbedded in strong adhesions near the side of the uterus. The Fallopian tube was not over an inch in length, much thickened, and convoluted. This was removed as closely as possible to the uterus and the stump cauterized. In searching for the right ovary the greatest care was used to separate the adhesions which densely involved all the tissues of that locality. In this effort, however, a cyst, as large as an orange perhaps, was ruptured. All efforts to find the right ovary failed, and we adopted the belief that it had degenerated into the cyst which had been so unfortunately ruptured. No effort was made to dissect out the walls of the cyst, which were strongly adherent to the bowels. The tube was removed in the same manner as before mentioned. The greatest caution was used in the toilet of the abdominal cavity, and the wound was closed with eight deep sutures of silver and Am Ende's dressings were applied. Although the operation was lengthy and the patient exhibited some shock, she rallied well the same afternoon, and, with a five-grain opium suppository, passed a comfortable but somewhat restless night. On the following morning she spoke cheerfully to me, remarking her freedom from pain. Pulse was 108, temperature 101°, respiration 24. At noon, same day, she presented evidence of becoming rapidly exhausted. Pulse 130, temperature 103°, respiration 30. Death occurred thirty-one hours after operation.

No urine was voided by this patient after the operation.

The attempt to relieve the bladder with the catheter was twice made, but resulted only in securing about an ounce of turbid, bloody urine. The urine in this case had been repeatedly subjected to rigid analysis, but nothing was revealed which necessarily militated against an operation unless, possibly, the scanty amounts of solids found.

An autopsy was made fourteen hours after death. The abdominal wound was apparently beginning to unite by the first intention throughout its entire length, and all the deeper structures presented a favorable appearance.

The kidneys were enlarged, and presented marked evidences of fatty degeneration.

The right ovary was not found, and it was believed, after a careful examination of the ruptured cyst, that it was the product of degeneration of the ovary.

Death was undoubtedly due in this case to the condition of the kidneys.*

Case IV.—*Pyosalpinx.*—E. H., twenty-three years of age, single, very delicate, and of nervous temperament. Had suffered almost from her first menstrual period, which began at an unusually early age.

Two or three years prior to this she had a severe attack of scarlet fever, followed by scarlatinal nephritis and dropsy. At this time some of the pelvic pains seemed to have originated,

* The operation in Case III was delayed from week to week on account of renal insufficiency.

Random specimens of urine showed nothing abnormal; but an examination of the total "out-put" for twenty-four hours invariably presented evidence of defective elimination of waste products.

Thus, for December 14, 1883:

Total quantity, 950 cubic centimetres; specific gravity, 1·019; solids, 38 grammes; urea, 19·5 grammes.

Acid; no albumin; no sugar; little coloring matter; oxalate of lime and a little pus in the sediment.

Numerous subsequent examinations merely served to verify the first analysis. The condition of the patient grew more and more unsupportable, and it was finally decided to grant her petition for the *dernier ressort.*

which, later on, as menstruation developed, became the more acute and fixed pains of her present disease.

I may say here, parenthetically, that, if scarlet fever can invade one portion of the genito-urinary apparatus, I think it fair to assume that other portions may also be affected, and I see no reason why the ovaries and Fallopian tubes should be exempt.

In this case menstruation was irregular—generally at intervals of about three weeks—and rarely lasted less than ten days. Her suffering at these times evoked the pity of all her friends, and they sought relief for her from numerous members of the profession. All the characteristic symptoms of localized pain, reflex irritation, nervousness, and weakness, which are indicative of ovarian and tubal disease, were abundantly manifest.

Two unusual concomitants of her disease attracted my attention:

First. As her periods approached, the lymphatic glands of the lower portion of her body and thighs became tender, and, in a day or two, this was followed by a general tumefaction of all the adjacent tissues. The labia were two or three times their normal size, and both limbs were swollen and painful to move. The inguinal region was specially sensitive. This seems to have been a *rhythmic neurosis*, dependent entirely upon the regular periods of pelvic engorgement and excitement to reproduce it.

Second. After the second or third day of menstruation the discharge would vary at times from the normal appearance and become muco-purulent and exceedingly offensive—so much so as to suggest the fœtid odor of malignant disease.

These two conditions would be maintained to the close of each period, then subside, giving no further inconvenience till the succeeding period.

Examination in this case revealed the cervix pressing against the neck of the bladder and rather firmly fixed by previous inflammatory processes, moderate retroflexion with prolapsus of left ovary, and great fullness and tenderness over tubal tracts and ovaries.

Operation, March 3, 1885.—This was accomplished rapidly. Some evidences of chronic pelvic peritonitis, deep-seated, but not sufficient to delay materially the operation. Both ovaries slightly enlarged, intensely engorged, and full of small cysts. These were removed, together with the tubes, as close to the uterus as it was possible to clamp and ligate.

Recovery from the effect of the operation was exceedingly prompt. The wound healed by the first intention, the temperature or pulse never rising above 100°.

Three months have elapsed now, and she has had no return of menstruation, beyond a slight molimen which appeared for two or three days after the operation. She, however, suffered from an attack of the rhythmic neurosis, previously mentioned, when her first month came around, but it was confined to one leg only, rather than both, as heretofore. This neurosis will probably soon cease entirely, as it is hoped and believed the majority of her previous discomforts will do.

Résumé.—There were four patients—two married and two unmarried.

Three lived, one died.

Two had extensive peritonitic adhesions; two had none.

Two have never menstruated since they were operated upon. One has continued to menstruate till the present time (about eighteen months), although the function has about ceased.

The one in whom the menstrual function has continued was one in whom the adhesions were very extensive; and perhaps this fact alone may have a bearing on the question of her prolonged menstruation. The two in whom the function ceased so promptly had no adhesions.

The prominent features of these cases are:

Case I.—Hystero-epilepsy. The prolonged menstruation after the operation.

Case II.—The asymmetry of the body.

Case III.—Salpingitis resulting from very severe malarial attack. Death from unsuspected renal disease.

Case IV.—Scarlatinal pyosalpinx.

The case of the last patient was particularly instructive from the peculiarities of the rhythmic neurosis and the fœtid discharge mentioned. I regret that I did not subject this discharge to Professor Ferguson's microscopical test for columnar ciliated epithelium, as it would have probably decided the question whether it was a drainage from a pyosalpinx, or the offensive discharge and detritus of a dysmenorrhœal membrane.

There appears to have been no special or positive evidence of gonorrhœal infection in a single one of these cases. I fully believe in the correctness of Dr. Noeggerath's statement, that there are great numbers of women who suffer from inflammations of the uterus and its annexa as a result of latent gonorrhœa, and I have now under my care ladies whose history makes it almost positively certain that their cases belong to this class; but the cases reported in this paper show that a considerable proportion at least *may* be autogenetic.

Mr. Lawson Tait has remarked that cases of diseased ovaries and oviducts can be relieved by nothing short of removal of the diseased organs; moreover, that these cases exist in great numbers, forming a large proportion of those in which the patients wander about from one practitioner to another seeking relief.

Mr. Tait has also supplemented this affirmation with a recent history of a large number of cases in which he has successfully removed the uterine appendages.

In the treatment, internal medication is practically valueless; nevertheless, we temporize with these cases for a while, using every fair endeavor to relieve pain and restore the function to a normal state. In early cases, where the patients are surrounded by every comfort and care, some are relieved, but the mass of them never find relief short of an operation.

In the study of Tait's operation and the causes which have demanded so heroic treatment the whole profession must be interested. They are no longer obliged to turn away women who beg for something—*anything*—to relieve their sufferings, by telling them "there is nothing more that can be done for you."

I believe there is scarcely an operation known to surgery which invites better ultimate results; the only trouble is, they expect these good results too soon.

This operation results in a climacterie to the patient. I think as much time should be allowed for a full recovery of the general health after an operation of this nature as would be required in the case of an ordinary natural climacteric. There are few women who do not feel nerve and pain discomforts for many months at the menopause, and these dis-

comforts are in exact ratio to the amount of possible disease existing in the uterus and its appendages at that time.

Since to bring about a menopause at an earlier age, by an operation for a disease, is an unnatural change, we may readily realize that at least as much time should be allowed for general recovery in the latter case as in the former.

I have been forcibly impressed with the enthusiasm with which the few upon whom I have performed this operation have accepted this serious alternative; in fact, after a short consideration of the subject, they have been unwilling to be put off with any other suggestions; they immediately see something tangible in this and are willing to risk their lives for the great stakes.

Fortunately, we are able to encourage them with almost a certainty of success.

All of these patients who are living have already demonstrated the success of the operation upon them. I happen to have seen during the past month two of them who live out of town; while neither is robust, both are free from the terrible distress in which they languished for so many years.

UMBILICAL HÆMORRHAGE.*

By WILLIAM HENRY THAYER, M. D.,
BROOKLYN.

Mrs. N., a young married woman, was delivered of her first child March 17, 1885. Both parents are healthy; the labor was normal, and the child apparently in normal condition. Its evacuations were sufficient, and the discharge from the bowels presented the usual appearance of meconium for four or five days. At the termination of the sixth day, March 23d, A. M., the nurse called my attention to its alvine evacuation, which was of a light slate-color, and its urine was slightly yellow. Its skin was slightly jaundiced. The child had taken the breast well, and had not vomited. The cord had not separated.

That afternoon there was a sudden and profuse hæmorrhage from the base of the cord, then beginning to separate. In my absence, Dr. G. R. Westbrook was summoned, and, failing to arrest the hæmorrhage with styptics, pinched up a fold of the skin and ligated it. At 10 P. M. I gave one grain of calomel At 4 A. M., 24th, the hæmorrhage began again, and, as I was ill, Dr. Westbrook saw the patient for me and repeated the ligature. I saw the child at 9 A. M. There was no hæmorrhage, but she was very pallid, and had had no dejection. I then prescribed ʒ jss. of castor-oil, and repeated doses of brandy and water. At 1 P. M. I was called, to find her again bleeding. The ligatures had not held; the cord was almost entirely separated, exposing a raw surface as large as a thumb-nail, livid, sodden, and with no appearance of coagulating. She had had several slight dejections, of nearly the same color as the day before, and she was extremely pallid and feeble. I transfixed the skin with surgeons' needles, two in the direction of the median line and one transversely, and around these I bound ligatures of silk, entirely controlling the hæmorrhage. But within an hour the patient began to sink, and died, without convulsion, at 7.30 P. M.

I assisted Dr. Westbrook in an autopsy at nine o'clock the next morning.

The intestines were much distended with gas; the stomach contained a little milk; the liver presented externally a normal appearance; the gall-bladder contained no bile, but only a small amount of mucus. The hepatic duct was pervious part of the way from the liver to the junction of the cystic duct; but its lower half and the entire length of the common duct were apparently an imperforate cord, as large as a coarse thread, and evidently impervious, as attempts to inflate it with a blow-pipe introduced into the gall-bladder were unsuccessful. The kidneys, heart, and lungs were normal in appearance.

The literature of this subject is confined to the last forty years, with the exception of two or three reports of single cases of fatal umbilical hæmorrhage, the earliest of which is by Mr. G. Watts, an English surgeon, in 1752. Dr. Cheyne published a case in Edinburgh, in 1801, of fatal umbilical hæmorrhage, with jaundice; and suggested that "the bleeding proceeded from the unhealthy change produced in the blood by the reception of the bile into the mass of fluids."

Since 1850 four papers have been published on the subject, based on cases collected from many sources. They are: One by Dr. Henry I. Bowditch ("Amer. Journal of the Medical Sciences," 1850), including twelve cases; Dr. Francis Minot ("Amer. Journal of the Medical Sciences," 1852), forty-six cases; Dr. Stephen Smith ("N. Y. Journal of Med.," etc., 1855), seventy-nine cases; and Dr. J. Foster Jenkins ("Trans. Am. Med. Asso.," 1858), one hundred and seventy-eight cases. I think Dr. Jenkins's report includes all the cases reported by the others. Dr. Jenkins says that in the Foundling Hospital at Paris, in 9,000 births there was only one case of umbilical hæmorrhage; in the Dublin Lying-in Hospital, in 6,654 births there were no cases; in the Emigrant's Refuge at Ward's Island, in 2,000 births there were two cases; in the practice of Dr. Charles Hooker, of New Haven, in 2,879 births there was one case; in the practice of Dr. Elisha P. Fearing, of Nantucket, in 4,000 births there was only one case. That is, in 24,533 births only five cases of umbilical hæmorrhage.

In Dr. Jenkins's table of one hundred and seventy-eight, most of the reports are incomplete. In thirty no history is given, except the facts of hæmorrhage and death. There were only twenty-two autopsies. Most of the reporters had no suspicion of the cause of the hæmorrhage; even in some of the autopsies the bile-ducts were not examined; the hæmorrhage was often attributed to patency of the umbilical vessels, and their condition is sometimes carefully noted. It is also frequently charged to a hæmorrhagic diathesis. Thus, Dr. Minot says: "Idiopathic hæmorrhage from the umbilicus is only one of the various manifestations of the hæmorrhagic diathesis, which in other cases is exhibited in bleeding from the gums, stomach, intestines, etc., and in the appearance of purpuric spots beneath the skin; in proof of this, we see the concurrence of these phenomena with umbilical hæmorrhage."

Now, in regard to these expressed opinions, it is to be said that closure of the umbilical vessels is chiefly the cicatrization of their orifices, which depends upon normal coagulation of blood; so that we must not stop at open orifices for the cause of the hæmorrhage, but inquire into the abnormal condition of the blood which interferes with its coagulation. It is probable that jaundice was present in all the cases. True, of the one hundred and forty-eight of Dr.

* Read before the Brooklyn Pathological Society, April 23, 1885.

Jenkins's cases in which any history is given, jaundice is mentioned in only seventy-seven; but Dr. Jenkins says that, "from the imperfect manner in which some of the histories are furnished, it is probable that a much larger proportion would be found in more fully recorded observations. Ninety-three per cent. of all who were reported to have jaundice died." Jenkins says: "It is a well-established fact that in almost all cases of jaundice the blood becomes much impoverished, the globules and the fibrin falling below the natural standard, and, consequent upon this impoverished state of the blood, a general disposition to hæmorrhage very commonly exists." Von Schueppel, in his article on the biliary passages ("Ziemssen," ix, 610), says: "The signs of a hæmorrhagic diathesis will rarely be missed in the long-continued icterus which is due to occlusion of the gall-duct. In many individuals, especially in very small children, the tendency to hæmorrhages makes itself felt soon after the beginning of jaundice."

In the twenty-two autopsies, the bile-ducts were examined in only eleven cases; in seven they were absent or impervious; in four they were open, but the liver was in an abnormal condition; in the cases where the ducts were pervious icterus had existed, with whitish dejections and bilious urine—indicating want of secreting power in the liver, although there was no impediment to its passage into the duodenum.

"Hæmorrhagic diathesis" is a misleading term, when the hæmorrhage is due to an accumulation of bile in the blood, whether from absence of the ducts or their complete obstruction with inspissated mucus, or to some abnormal condition of the liver which causes a suspension of its functions. Dr. Jenkins says: "Of families known as 'bleeders,' where the slightest injuries often induce serious hæmorrhage, scarce any record exists of infantile umbilical bleeding." Instead of a hæmorrhagic diathesis in the cases which are the subject of this paper, there is sufficient evidence already adduced that the cause is in the liver or its ducts.

Among the cases reported by Dr. Jenkins are those of thirty-nine children of seventeen mothers, each of whom bore more than one child who had umbilical hæmorrhage. No one of these mothers had exhibited any hæmorrhagic tendency; many of them had borne other children who had no hæmorrhage. In nineteen of the cases jaundice is reported present. In only two cases is it expressly stated that there was no jaundice, but in these cases, which were in twins, death occurred in seventy-two hours after birth from hæmorrhage through the unbroken surface of the cord;* in four cases of the six which were examined post mortem the ducts were found impervious; two of these were in children of the same mother. All the evidence we get from these cases shows a tendency to biliary obstruction, which may exist in certain families, rather than a hæmorrhagic diathesis.

An occasional cause of fatal umbilical hæmorrhage is acute fatty degeneration near the close of fœtal life, including the heart, lungs, liver, and kidneys, the blood-vessels breaking down everywhere, with resulting hæmorrhages. Such a case was reported by Dr. Mary Putnam Jacobi, in which hæmorrhage began four hours after birth, and death occurred in less than twenty-four hours. Dr. Jacobi quotes Hecker and Buhl as describing this disease in 1861 ("Am. Jour. of Obstetrics," July, 1878).

In addition to a certain proportion of cases which are hopeless, from absence or obliteration of the common duct or the hepatic duct, or from the general fatty degeneration just referred to, there are many in which the ducts are plugged with inspissated mucus, or closed by thickening of the mucous membrane, the result of catarrhal inflammation, to which relief may come spontaneously or by medical treatment. Of one hundred and seventy-eight patients, thirty recovered, and many of the fatal cases were of such a character that recovery would have been possible—that is, the obstruction was of a temporary nature.*

It is safe to conclude that in cases of umbilical hæmorrhage in new-born children, attended with jaundice, the cause of the hæmorrhage is usually the accumulation of bile in the blood, produced by obstruction of the hepatic or the common duct, or by an abnormal condition of the liver.

As to the general history of these cases, hæmorrhage began at the root of the cord, either when the separation commenced or within a few days after; the average time was the eighth day, but in seven cases it did not begin till the third week; in one case eight weeks from birth. Dr. Murchison, in his work on "Diseases of the Liver," relates the case of a child who died at the age of four months and a half, having had jaundice from its first week, with progressive emaciation, after a while diarrhœa, the discharges being perfectly white, frequent epistaxis, vomiting of blood, and ecchymoses under the skin, ever increasing in number. The bile-duct was found to be completely obliterated, its place being occupied by a small quantity of areolar tissue.

The average duration of the hæmorrhage in the fatal cases was three days and a half. In a large proportion of the cases there was jaundice several days before the hæmorrhage began; in many of them purpura, either before or after the hæmorrhage, and passages of blood from the stomach or bowels. Constipation was frequent; the stools were white or clay-colored; the urine was deeply stained with bile.

As to treatment, the first indication is to transfix the integuments at the base of the cord with needles, and carry a figure-of-eight ligature underneath them. Styptics and compression are of no avail. But Dr. Jenkins, who advocates the ligature, cautions us not to stop with that, but to use such internal remedies as may relieve the liver, where no anatomical malformation exists. Chief of these are nitro-hydrochloric acid and tincture of the chloride of iron, with cathartics, especially calomel.

* Probably from general fatty degeneration, as in Dr. Jacobi's case.

* Illustrative of a fatal closure of the bile-ducts with inspissated mucus, I recall the case of an infant who died a few days after birth with symptoms of intestinal obstruction, at whose autopsy I found complete closure of the ileo-cæcal valve, the entire small intestine being distended with gas, and the whole large intestine completely empty and contracted. It was at first supposed that the intestine was impervious by malformation, but washing removed an accumulation of mucus and disclosed the valve in a normal state.

THE DUCTUS CHOLEDOCHUS COMMUNIS OBSTRUCTED BY A CALCULUS; JAUNDICE; DEATH; NECROPSY; REMARKS.*

By H. D. BLISS, M. D.,
BROOKLYN.

The case occurred in St. John's Hospital. The clinical history is kindly furnished me by Dr. R. L. Casburn, the house physician, from his notes:

History.—November 1, 1885, Frank W., a German, aged sixty-five years; history good; no sickness except as noted below. Has been for two or three years an assistant in the male ward. He was admitted to the hospital for the treatment of a large varicose ulcer of the leg of many years' standing. It encircles the leg to within an inch, is of irregular shape, and varies from one to four inches in breadth. The ulcer proved very intractable, and remains now probably in about the same condition as when he entered the hospital. This is his only complaint, and causes him remarkably little trouble. The patient is a well-preserved man for his age; is about five feet and a half in height, weighs 180 pounds, and has a tendency to become obese.

About this time, November 1st, he was taken with a sudden attack of marked jaundice. The accompanying symptoms were not such that an accurate diagnosis of its cause could be made. After the jaundice became very marked there were nausea, anorexia, slowness of the pulse, constipation, clay-colored stools, and high-colored urine. There was no enlargement of the liver, and no tumor that could be detected. He complained of no pain anywhere, unless it was a slight headache. There was not even tenderness over the hepatic region. Dr. William Wallace, attending physician on duty, thinking it might be due to torpid liver or catarrhal condition of the common bile-duct, applied blisters over the site of the duct and gave calomel freely; at first it seemed to avail nothing; after about two weeks the jaundice suddenly commenced to give way and soon entirely disappeared, and the patient was as well as ever. He remained quite well until December 10th, when another attack of jaundice suddenly came on, like the previous attack, accompanied by all the symptoms which necessarily accompany jaundice from any cause, but by no symptoms from which a special cause could be diagnosed. The same treatment was instituted as before, but, as he got no better, it was changed to acid. nitro-hydrochlo. dil., ℥xv, t. i. d., and cloths saturated with a lotion of the same were applied to the region of the liver. This was continued for about a week with no improvement. Treatment was then changed to ℞ Sodii phosphatis, ʒ j, t. i. d., dissolved in a glass of water; this was persisted in for two weeks without any apparent result. The troublesome symptoms had all increased; the jaundice was about as marked as it could be; the appetite entirely gone; nausea was constant; bowels constipated, except when violent cathartics were employed; stools clay-colored all the time; urine very high colored; pulse slow, fifty and under. Patient becoming emaciated, and certainly failing slowly.

On January 16, 1885, between five and six weeks from the time of the present attack, a consultation was held by Dr. William Wallace, Dr. Arnold W. Catlin, and Dr. Frederick H. Colton, attending physicians to the hospital. It was decided that small, often-repeated doses of the mild chloride be given and pushed to slight salivation. Accordingly, gr. $\frac{1}{20}$ was given every hour. But the jaundice did not yield in the least, even with the touching of the gums.

From this time on the symptoms only were treated, the patient being made as comfortable as possible; but he kept gradually failing, and died on February 13, 1885—a little over two months from the beginning of the second attack.

Necropsy.—The body was much emaciated. On opening the thoracic cavity, the heart was found normal, the lungs crepitant throughout and normal, except a few old pleuritic adhesions. The abdominal cavity, on inspection, showed that the liver was not enlarged, and was natural in color. The intestines were light in color, almost a grayish white. On examination, the gall-bladder was found to be distended, but not enlarged, and of a dull, muddy color. On opening the bladder, it was found to contain a brownish, muddy-colored fluid of greater consistence than bile. Further examination revealed a stone encysted in the common duct. It could not be pushed forward or backward, and acted as a ball-valve; the walls of the cyst were a pyogenic membrane, and the stone was bathed in pus. The stone was a regular ovoid, a little over three quarters of an inch in the longer diameter, and a little less than three quarters of an inch in the shorter diameter, roughened on the outside, with elevations like small grains of sand, with the angles worn off. The stone was as hard as an ordinary marble, and, after being thoroughly dried, sunk readily in water.

The stomach was contracted; the intestines contained a quantity of thick, putty-colored material; spleen normal; pancreas elongated and narrow. The kidneys contained many cysts between the parenchyma and capsule of the size of a five-cent piece to a twenty-five-cent piece, containing a clear fluid. In the pelvis of the right kidney was a calculus, and in the left two calculi, irregular in shape, smooth, and slate-colored, measuring about half an inch on the longest facette. The organs not mentioned were normal.

Remarks.—The question now presents itself, What additional means could have been employed to assist in making a diagnosis, and, had a diagnosis been made, how would it have affected the treatment? Bartholow (Pepper's "System of Medicine," vol. ii, p. 108) says he has "punctured the gall-bladder with a fine exploring trocar, removed the contents, and explored the interior without damaging the organ." Had this been done, it is doubtful if the stone would have been discovered. On account of the hardness of the stone, it would have been impossible to dissolve it had it been discovered. The question is, All other means failing, would abdominal section have been justifiable? Henry Morris ("International Encyclopædia of Surgery," vol. v, p. 886) says: "Laparotomy, followed up by suture or removal of the gall-bladder, ought, in certain cases, to be adopted." Again, page 1071: "In cases of distension with pus and calculi, and in those instances of accumulation of bile or mucus, in which other remedies have failed, operative measures will be required."

It may also be worthy of note that there had been no pain; and that during life there had been no signs referable to the kidneys, and examination of the urine gave no evidence of the renal calculi.

57 Madison Street.

* Read before the Brooklyn Pathological Society, March 12, 1885.

An Anti-Vaccinator.—It is said that one Dr. Ross, who has caused much trouble in Montreal, was found, on being made to bare his arm, to have not only marks of former successful vaccinations, but evidences of one of recent date.

APHONIA SIMULATED IN THE YOUNG.

By LOUIS KOLIPINSKI, M. D.,
CHILDREN'S HOSPITAL, WASHINGTON, D. C.

The following cases are reported to illustrate the feigning of disease by the young. They further show the impossibility of impressing upon alarmed and anxious relatives the truth of such deception, and may finally remind the practitioner, called in haste, that, instead of a disease, he may merely have an impostor to treat.

A female mulatto of eighteen was presented by her lover, with the statement that she had been suddenly seized with loss of speech on the preceding night, and that she had not since uttered syllable or sound. A careful examination of her general health, past and present, did not disclose any cause for the aphonia. Her hearing was normal, and she readily responded to questions in writing and by signs. Neither she nor her companion gave the least support to the suspicion of hysteria as the cause. Her facial expression was calm and composed, and there was no outward evidence of uneasiness or fear.

In the absence of every conceivable factor of a genuine aphonia, I concluded that it was a case of malingering with the purpose of exciting the alarm and sympathy of some one. Acting on this presumption, her escort was excluded from the room and the attempt made to loosen her tongue by persuasion. All efforts failed; there remained but the last resort of intimidation. She was assured that repeated applications of a laryngoscopic throat mirror sufficiently heated would restore her voice. She bore a few introductions with considerable courage, but soon perceiving, by the persistency of the applications, that I was confident of success, she at last began speaking in monosyllables, and, in conclusion, narrated the cause of her trouble as the result of a quarrel with her lover. All efforts to make her confess that her silence had been only voluntary were useless. Her companion, who had exhibited the utmost solicitude for her, was overjoyed at the speedy cure.

I was called to see a negro boy of eight years who had become suddenly mute a few hours before. The other members of the house were much alarmed, and the mother was so agitated that it was with difficulty that a history could be obtained. The boy had recently had Rötheln, which was followed by a bronchitis, but was thought to have recovered. Nothing had occurred, my informant said, that could have possibly induced the child to become mute either from anger or disappointment, and yet a search for other causes was fruitless. The patient lay on a couch placid and at ease. Recollecting the experience in the former case, I became convinced that this was a similar one. The room was therefore cleared, and I attempted to elicit a word by a variety of arguments and questions. The result was a signal failure. The boy maintained a stolid look and answered only with motions of the head. A forcible introduction into the mouth of a spoon-handle and the threat of a hot iron were of more avail. In his alarm he began to cry for his mother. She, however, could not be made to believe that the boy had been feigning, and her surprise and pleasure at his recovery were only equal to her first distress.

Both cases were from a low class of society. The dissimilar ages, the negative characters of their histories, and the bearing of the patients were sufficient to exclude any disease or morbid state in the causation. It was apparent that the object of the sudden and complete loss of speech was intended to excite the alarm of their connections, and thereby gain some point by awakening solicitude. It was impossible in the boy's instance to confirm this by individual statement of mother or child.

But, whatever the motive, the malingering was successful, for it was soon evident to me that the superstitious minds of the interested ones were proof against every assurance that the aphonia was not real, and that they had been deceived.

To conclude, the mutism which both selected as the startling affliction is the most natural one imaginable. The patients were not sufficiently cultivated to counterfeit some disease requiring knowledge and judgment for skillful imitation, as, for example, blindness or deafness. Children of a bashful disposition, as everybody knows, are mute in the presence of strangers, and our subjects simply repeated what they perhaps had often practiced before, but from different motives. It was the half-voluntary, half-instinctive act of an uneducated mind.

Book Notices.

Topographical Anatomy of the Brain. By J. C. Dalton, M. D., Professor Emeritus of Physiology in the College of Physicians and Surgeons, New York, and President of the College. Philadelphia: Lea Brothers & Co., 1885. Three Volumes, 4to, pp. vii–56; iv–59 to 104, inclusive; iv–115 to 175, inclusive. Heliotype Plates.

This work is unquestionably one of the most creditable contributions ever made to the study of the anatomy of the brain. We know not which most to admire—the beautiful execution of the heliotype reproductions from photographic negatives made under the author's supervision from fresh preparations of his own, or the skill that arranged the preparations in such manner as to make them tell their story so effectively. From either point of view, the work is altogether beyond criticism. We can only express our satisfaction that, after years of labor as a teacher, the pioneer of experimental physiology in America should have found time to finish such a great undertaking—one that will go far toward wiping away from our medical literature the reproach that it ignores research and lends itself only to that which makes a direct practical appeal to the multitude. Not the least satisfactory part of the work is that in which the author describes his methods of making parallel sections of the brain—a portion that is very effectively illustrated with woodcuts. The publishers are deserving of the greatest praise for the appearance of the volumes.

BOOKS AND PAMPHLETS RECEIVED.

The Science and Art of Midwifery. By William Thomson Lusk, A. M., M. D., Professor of Obstetrics and the Diseases of Women and Children in the Bellevue Hospital Medical College, etc. New Edition, Revised and Enlarged. With Numerous Illustrations. New York: D. Appleton & Co., 1885. Pp. xviii–763. [Price, cloth, $5; sheep, $6.]

The Essentials of Histology, Descriptive and Practical, for the Use of Students. By E. A. Schäfer, F. R. S., Jedrell Professor of Physiology in University College, etc. Philadelphia: Lea Brothers & Co., 1885. Pp. viii–245.

Laparotomy for Ovarian Cyst. By A. W. Leighton, M. D., New Haven, Conn. [From the Proceedings of the Connecticut Medical Society, 1885.] Pp. 4.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D. Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, OCTOBER 17, 1885.

NO MORE CODE CONTROVERSY.

In this issue of the Journal we print a letter which deals with a subject that we have long considered a good one to be let alone, so far as public discussion of it is concerned. On that account we have for many months past uniformly declined to publish letters on that subject, no matter what ground was taken in them, and we now make this solitary exception, first, because Dr. Black's letter seems to embody only the convictions of a pure-minded man who has no axe to grind, and whose purpose does not appear to include any attempt to crack the code whip, and, secondly, because we believe our correspondent to be so conscientious as readily to admit to himself that he may possibly have given Dr. Jacobi's remarks a wider application than their author really intended. We do not doubt that Dr. Black's ideas as to the propriety of consultations with so-called homœopathists—using the word consultation in its legitimate meaning—are quite in accord with those held by, as he says, "ninety per cent.," not only of the physicians of his own region, but of those of the whole country, including an overwhelming majority even of the new-code men. We believe, moreover, that Dr. Jacobi would be among the last to advocate such "consultations." But no man's position on that abstract question can quite cover the field that has been the ground of the contention in this State, and we consider it an utterly hopeless task to attempt to make that field clear to our brethren in other parts of the country. For that reason we deprecate any further controversy in the matter. The New York code has now been in operation for three or four years. Let its working be kept under observation for five, ten, fifteen, or twenty years more; and then let the question be decided whether its effect has been good or evil. Meantime, let there be no further contention from theoretical points of view, and let there be no more attempts to ostracize men because of their opinions on the question, be they what they may. For our part, so far as public controversy is concerned, we shall regard the code as a dead issue.

A GERMAN CRITICISM OF AMERICAN MIDWIFERY.

It is generally felt to be an occasion for regret when one has to quote an author at second hand. Especially is this held to be the case when the subject treated of relates to science. Most of all to be avoided is criticism founded on a second-hand quotation, particularly when the version drawn upon does not purport to give the original in full, but only in abstract. We regret that on such a flimsy foundation a contributor to one of our most valued German contemporaries has recently seen fit to indulge in criticism of a New York practitioner.

In our issue of April 26, 1884, we published a report of the proceedings of a meeting of the New York County Medical Association, including a summary of a paper, by Dr. Charles A. Leale, entitled "Scarlatina of the Fœtus in Utero and of the Mother at the Ninth Month of Pregnancy." In this paper Dr. Leale gave the history of a case, in the course of which he said: "The fœtus, from its violent motions, appeared to be in convulsions. The mother became delirious. It was considered necessary to deliver quickly in order to save either the mother or the child. The cervix was accordingly dilated, and within four hours the forceps was applied and the child extracted, without injuring mother or child."

The "Revne de médecine" for July, 1885, summarizes our account of the history of the case, and says: "*Le fœtus s'agitant beaucoup et paraissant en convulsions, on fit la dilatation du col et on put extraire l'enfant sans dommages ni pour lui ni pour la mère.*" This is correct, so far as it goes, but it omits the sentences which showed that rapid delivery was considered essential to the mother's safety, and that that opinion was well founded on the clinical facts. As regards the *accouchement forcé*, our French contemporary implies—which evidently was all that Dr. Leale meant to say—that the processes of dilatation and extraction did not injnre either the mother or the child.

The "Deutsche Medizinal-Zeitung" gives the following translation of the French journal's words: "*Da der Fötus sich sehr stark bewegte und Konvulsionen zu haben schien, machte man die Dilatation des Kollum und konnte das Kind extrahiren, ohne Schaden für Mutter und Kind.*" To judge from this account—and we admit that it is a perfect translation of the French version—*accouchement forcé* was performed solely in the interest of the child, the statements as to the mother's desperate condition not having found a place in the French summary of Dr. Leale's remarks. Thus far, then, the German journal is simply proceeding upon insufficient information, and it might perhaps be held that, in the absence of the full statement of the facts, it would have been justified, but for the manifest impropriety of founding any criticism upon a mere summary, in questioning the propriety of the resort to forcible delivery. But we are unable to see that anything can warrant its assumption that the mother's death was in any way incompatible with Dr. Leale's statement that the operative procedures resorted to were accomplished "without injuring mother or child." But it is on that assumption that it seems to have founded the following remark: "(*Und da soll die amerikanisch indizirte forcirte Entbindung ohne Schaden für die Mutter gewesen sein?!!*)"

Damaging as the phrase "*amerikanisch indizirte*," the note of interrogation, and the two exclamation marks may appear to the German mind, we would like to ask our Berlin contemporary if it regards the death of a patient who has been operated on as necessarily indicating that the operation was the cause of the fatal result.

MINOR PARAGRAPHS.

THE TENNESSEE "STATE BOARD OF HEALTH BULLETIN."

We have received the first number of this periodical, for the month ending July 31, 1885. It seems to owe its origin to the fact that the publication of the monthly meteorological report of the State (which was formerly published with the crop reports, by the Bureau of Agriculture, Statistics, and Mines, and more recently in an agricultural newspaper) has lately been turned over to the board. The board therefore concluded to couple its weather reports with matters more properly appertaining to its own sphere of action, and the result is this pamphlet of twelve pages of reading matter. We regret to see that the appropriation made by the State for sanitary purposes was so small as to compel the board to admit advertisements into this, a public document. Sanitary information ought certainly to be diffused as generally and as systematically as possible; hence the State would find its account in not being niggardly in the matter of this excellent publication.

THE NEW VOLUME OF THE INDEX-CATALOGUE.

The appearance of the sixth volume of this great work is a fresh reminder of the wonderful zeal with which it has been prosecuted, and it is almost superfluous to say that it reveals the same painstaking accuracy that marked the preceding volumes. The work is now brought down to the word Insfeldt. The additional list of medical periodicals drawn upon fills eleven of the large pages, and shows the completeness with which contemporary periodical literature is indexed. The work is simply stupendous, and we can only repeat the expression of our sense of the obligation under which the whole profession ought to feel itself to Dr. Billings and his associates in the undertaking. We may now reasonably look forward to the completion of the catalogue in the course of a few years more, and it is earnestly to be hoped that the Government will do everything in its power to hasten its publication.

THE DISINFECTION OF IMPORTED RAGS.

No doubt there has been some needless quarreling over the matter of the disinfection of foreign rags entered at the port of New York, but it must be conceded, we think, that the importers have been unreasonably tantalized by the course that the Commissioners and the Health Officer of the Port have seen fit to pursue. This we say without any reference to the charges that these officials have played into the hands of a particular company holding the patent of a disinfecting process. We are not surprised to learn, therefore, that the importers have at last shown a disposition to take the matter to the courts for adjudication. We sincerely trust that the outcome of the contention will be to block the game of those who seem to be seeking to still further handicap a port that nothing but the most bountiful provisions of Nature could have saved thus far from the rapacity of the politicians.

THE DANGER OF SMALL-POX FROM CANADA.

We can scarcely overlook the magnitude and the pressing urgency of the danger of the Canadian outbreak of small-pox gaining access to our own territory. Much will depend upon the vigilance and the intelligence displayed at a few important points, particularly Buffalo. We are glad to learn, therefore, that the sanitary officials of that city seem fully alive to the exigency, and that their efforts are meeting with hearty cooperation at the hands of the Canadian authorities. We remember that Buffalo was one of the best-managed places in the great epidemic of 1872–1873, and we have no doubt that its citizens may be depended upon to call into play, if necessary, the individuals and the machinery that served so well at that time.

A NEW MEDICAL JOURNAL IN BUFFALO.

We have received the first number of a new monthly journal, entitled "The Medical Press of Western New York," published in Buffalo. It is edited by Dr. Roswell Park, of Buffalo, assisted by Dr. M. D. Mann, of Buffalo, Dr. Ely Van de Warker, of Syracuse, and Dr. W. J. Herriman, of Rochester. These gentlemen make a very strong staff, and we look to see the new journal take a very high position. Of the first number, dated November, 1885, we can say that it augurs exceedingly well.

A FLORIDA MEDICAL JOURNAL.

It is announced that the first number of a monthly journal of sixty pages, to be styled the "Florida Medical and Surgical Journal," will be published at Jacksonville on the 1st of November. It is to be edited by Dr. T. O. Summers, Dr. C. H. Mallett, and Dr. Neal Mitchell, who promise that no efforts will be spared to make it "a faithful exponent of the highest interests of the profession throughout the State." A feature of the journal, and one that can be made very valuable, is to be the supplying of information concerning the influence of the Peninsular climate.

NEWS ITEMS, ETC.

The American Academy of Medicine will hold its next meeting in New York on Wednesday and Thursday, the 28th and 29th inst.

The New York State Medical Association will hold its second annual meeting in New York on Tuesday, Wednesday, Thursday, and Friday, November 17th, 18th, 19th, and 20th. The last day's session will be held at the Carnegie Laboratory, and the others at the Murray Hill Hotel.

The Medico-Chirurgical College of Philadelphia.—We learn that Dr. Frank Woodbury, the editor of the "Medical Times," of Philadelphia, has been appointed professor of materia medica and therapeutics.

The Journal of the American Medical Association.—Dr. William Lee, who, from the beginning, has been assistant editor of the association "Journal," has, we understand, been dismissed by the editor. Dr. Lee was appointed by the original committee a member of the council of the Section in Physiology of the Ninth International Medical Congress, but resigned after the Chicago meeting of the New Orleans committee.

The British Gynæcological Society.—Dr. Fordyce Barker, Dr. T. Gaillard Thomas, and Dr. Thomas Addis Emmet, of New York, and Dr. William Goodell, of Philadelphia, have been elected honorary fellows.

Cremation was the subject of an interesting paper, by Dr. William M. McLaury, read before the Society of Medical Jurisprudence and State Medicine on Thursday evening of last week.

The Preventive Inoculation of Hydrophobia.—A recent issue of "Science" contains an extract from a letter lately written by M. Pasteur, in which he expresses his confidence in his method of preventing hydrophobia, even when applied so late as a fortnight after the bite. As yet, he has made only one trial of it on the human subject—in the case of a boy who had

been bitten horribly on the 4th of last July, and whose death by hydrophobia seemed unavoidable, but who, up to the time the letter was written, September 7th, had continued in excellent health.

The Marine-Hospital Bureau's Health Reports, up to Tuesday, the 13th, show that yellow fever is epidemic in Caracas, and has appeared at Acapulco; that the cholera in Spain is abating, and has wholly disappeared in Valencia; and that small-pox is raging in Buenos Ayres.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 4 to October 10, 1885:*

Weisel, Daniel, Captain and Assistant Surgeon. To be relieved from duty at camp at Rock Springs, Wyoming, and return to his proper station, Fort Fred. Steele, Wyoming. S. O. 99, Department of the Platte, October 1, 1885.

Adair, George W., Captain and Assistant Surgeon. Leave of absence extended one month. S. O. 232, A. G. O., October 9, 1885.

Biart, Victor, Captain and Assistant Surgeon. Sick leave of absence further extended six months on surgeon's certificate of disability. S. O. 227, A. G. O., October 3, 1885.

Bushnell, G. E., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 215, Department of the East, October 6, 1885.

Stephenson, William, First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Niobrara, Nebraska, and ordered for duty at camp at Rock Springs, Wyoming. S. O. 99, Department of the Platte, October 1, 1885.

Chapin, A. R., First Lieutenant and Assistant Surgeon. Leave of absence extended one month. S. O. 230, A. G. O., October 7, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 10, 1885.*

Bright, George A., Surgeon. Ordered to U. S. S. Brooklyn.

Fitts, Henry B., Assistant Surgeon. Ordered to Naval Hospital, New York.

Hall, John H., Passed Assistant Surgeon. Detached from Naval Hospital, Mare Island, California, and ordered to the Hartford.

Swan, Robert, Passed Assistant Surgeon. Detached from Naval Hospital, New York, and ordered to the Brooklyn.

Society Meetings for the Coming Week:

Monday, *October 19th:* New York County Medical Association; Medico-Chirurgical Society of German Physicians; Hartford, Conn., City Medical Association; Chicago Medical Society.

Tuesday, *October 20th:* New York Academy of Medicine (section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Societies of the Counties of Kings and Westchester (White Plains), N. Y.; Medical Society of Hunterdon County (Flemington), N. J.; Ogdensburg, N. Y., Medical Association.

Wednesday, *October 21st:* Northwestern Medical and Surgical Society of New York (private); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society (clinico-pathological).

Thursday, *October 22d:* New York Academy of Medicine (section in Obstetrics and Diseases of Women and Children); Harlem Medical Association of the City of New York; New York Orthopædic Society; Roxbury, Mass., Society for Medical Improvement (private); Brooklyn Pathological Society; Pathological Society of Philadelphia.

Friday, *October 23d:* Yorkville Medical Association (private); New York Society of German Physicians; New York Clinical Society (private); Philadelphia Clinical Society; Philadelphia Laryngological Society.

Saturday, *October 24th:* New York Medical and Surgical Society.

Letters to the Editor.

THE NEW YORK CODE OF ETHICS.

Newark, Ohio.

To the Editor of the New York Medical Journal:

Sir: Dr. Jacobi's remarks, in his able address in your issue of October 3d, on the International Congress, will not fail to find a sympathetic echo in the heart of every true physician; but, in common with others, I can not help an exclamation of surprise at what he says on the war of the codes, or of the "unexpected success on the part of the profession of the State of New York in harmonizing a large majority of the medical men of the United States." What his grounds are for this assertion, I have only his own inadequate explanation, which is, at least in part, grounded on a misapprehension, and one, too, that is fundamental, so far as the issue is concerned between the New York and the national codes of ethics. He says that homœopathists now maintain that "their practice is not based on an exclusive dogma." If the adherents to that ism in New York have progressed that far, they are to be congratulated, and it is to be hoped that this advance will soon be followed by another—to discard the trade-mark of their sect. Now, Dr. Jacobi seems to take it as a matter of course that the liberalization of homœopathy in his State warrants the conclusion that it has extended to all the States. In other words, as goes New York so goes the whole country—a somewhat exaggerated form of cockneyism. During a long and not very limited acquaintance with homœopaths in this region, I have only found one of the kind he mentions, and he is a half-breed.

Put this question to homœopathic practitioners—not to be answered by some spread-eagle orator in a public assembly, but by the working men with whom we are brought into daily relations—Are you willing in consultations to use large or small doses of medicines, to order purgatives or emetics, or to employ the lancet, if the large majority of the most eminent physicians the world over testify strongly in their favor in appropriate cases? The homœopath instantly replies, No, if by a majority of eminent medical men you mean allopaths. Now, I venture to assert that this would be the reply of ninety per cent. of the homœopaths with whom we in this region are brought into contact. The New York code says: You may meet such men in consultation. What for? To try to reconcile irreconcilable differences; to argue and get into unseemly quarrels in the sick-room; or with oily suavity yield up your convictions of what will most likely save life, for the sake of a fee? The homœopath, in such an instance, would be by far the more honorable of the two. I say emphatically that in this region the regular physician who meets a homœopath in consultation must do one or the other of these things, and the New York code of honor says he may. Away with such a consent to a course of conduct that must lower the *morale* of the profession, and, when I say this, I am confident that I have at least ninety per cent. of the profession at my back.

J. R. Black.

PRIZE ESSAYS ON DISINFECTANTS.

199 Dean Street, Brooklyn, N. Y., *October 5, 1885.*

To the Editor of the New York Medical Journal:

Sir: I desire to call the attention of the profession to a flagrant exhibition of what must either be favoritism, ignorance, or a culpable disregard of all justice. I allude to the decision of the prize committee appointed by the publisher of the "Druggists' Circular" for the proper awarding of three graded prizes to the best three essays on disinfectants. All competing essays have been printed in a neat volume of 168 pages. The first prize was awarded to essay No. 6, written by a non-medical man, and a former editor, I believe, of the paper offering the prizes. His essay is a heterogeneous rehash of old and new opinions and recommendations on disinfectants and antiseptics. He seems to have succeeded in impressing the committee by his long array of references, many of which are useless and unscientific. The second and third prizes were awarded to two physicians, and both their essays were worthy, in fact the only such in the collection. The rest of the work is composed mainly of trash. Essay No. 21 covers but one page. I am astounded at the committee's decision, as Dr. Baker, of Lansing, Mich. was one of the examiners. No. 6 is thoroughly unscientific, and fails to agree with the terms upon which the award was promised to be made. That such a decision is not without gross risks is apparent when we consider that the druggists, to whom the people go for disinfectants, rely upon the judgment of the awarding committee as to which is the best essay, and by this they will be guided. Since the public are in this way at the mercy of the druggists, I have written you in the hope that others may be directed to this matter, and that such able authorities as Dr. Sternberg, Dr. Salmon, Dr. Duggan, and others will set upon it the seal of their condemnation. The two essays that received the lower prizes have the merit of being up to the times and giving sound sanitary advice. Could the pharmacists be taught to prepare their disinfectants of the materials these two advise, much good certainly would be done, and many lives saved. The first-prize essay is so poor, compared to the other two, that it can not be compared with them. It is a shallow, hurried, carelessly written compilation. I do not see that the writer deserves any blame—he is a layman, and can not know as much about the subject as an intelligent physician. I do think, though, that the committee deserves everlasting discredit for the work it has done, and I regret that its work is stamped with the seal of Dr. Baker's approval. Trusting that this will be "passed along," I have the honor to be,

Very respectfully yours,

A. H. P. Leuf.

Proceedings of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Meeting of September 28, 1885.

The President, Dr. Daniel Lewis, in the Chair.

Nominations were made as follows: For President, Daniel Lewis; for Vice-President, Laurence Johnson; for Secretary, Wesley M. Carpenter; for Assistant Secretary, Charles H. Avery and Robert Campbell; for Treasurer, O. B. Douglas; for Censors (five to be elected), H. T. Peirce, W. E. Bullard, W. O. Moore, H. B. Conrad, W. Wells, H. G. Piffard, and J. W. Howe.

Gonorrhœa in Women.—Dr. A. F. Currier read a paper with this title. [See p. 424.]

Dr. H. T. Hanks regarded the question of the ætiology of gonorrhœa as still undecided, but the pathological results of the disease and the indications for treatment were not doubtful. He believed with Dr. Currier that a very large percentage of all diseases peculiar to women were due to gonorrhœa. In dispensary practice one would see patients who had had acute gonorrhœa return some years afterward suffering from troubles which had their origin in such acute inflammation. He did not believe that any physician, without the aid of the microscope, could make a sufficiently accurate diagnosis of gonorrhœa. But, as to the pathological results of acute gonorrhœal inflammation, he thought we should feel more confidence in our ability to treat them successfully. He would beg leave to differ with Dr. Currier with regard to the relative frequency of gonorrhœal endometritis and urethritis. He regarded the latter affection as far the more frequent. If the circum-uterine tissues, the Fallopian tubes, and ovaries became affected, we could do much by judicious treatment—as by applications of iodine, glycerin, chlorate of potassium, etc. In the treatment of the disease in its acute stage, he agreed with the author of the paper in the use of vaginal injections of chlorate of potassium, or carbolic acid, corrosive sublimate, etc. The treatment should be systematic, the injections being made every four hours.

Dr. H. J. Garrigues had not looked for gonococci, but had been enabled to make the diagnosis between simple elytritis and gonorrhœa by the more virulent symptoms of the latter. He often found Bartholin's glands affected, and found it necessary to open them and make applications. The most effectual vaginal injection for the acute disease was a solution of bichloride of mercury, one to two thousand; but other agents had also proved efficacious in his hands. As to the involvement of the urethra, he agreed with Dr. Currier that it was not often present. For the disease in the uterus he applied Churchill's tincture of iodine. As to the efficiency of medicated pads, he thought the glycerin was probably the efficient agent rather than the medicine which it contained.

Dr. H. J. Boldt thought urethritis was more common than the remarks of the gentlemen would lead us to suppose. The majority of cases of acute gonorrhœa would not end in less than three months.

Dr. Lyttle said it had been stated that we must depend upon the clinical phenomena in making a diagnosis; he failed to see, therefore, the value of the gonococcus. The treatment was the same as that which had been adopted before the discovery of that microbe.

Dr. Messenger had never seen a patient upon whom he could rely for making proper vaginal injections; the physician should carry out the treatment himself, and make the injections thorough. The syringe which he used was described as being specially valuable in enabling one to fully balloon the vagina with the bichloride solution.

Dr. Currier closed the discussion, and said he was not sure that glycerin did not play an important part in the treatment when it was employed as a vehicle for other medicines. The value of the gonococcus in diagnosis would be specially seen in cases brought into the courts.

The Treatment of Leprosy.—Dr. G. H. Fox read a paper on this subject, in which he deprecated the tendency to depress the patient morally by giving him to understand that his disease was incurable, and by making him an outcast from society or confining him with those affected in like manner. The patient's *morale* was of far greater importance than change of climate, attention to food, etc.—conditions which were considered necessary to his welfare. He gave the history of a missionary to the

Sandwich Islands who contracted leprosy. The symptoms had become well marked, but he was given to understand that his case was not hopeless and that he should not be put under restraint, and chaulmoogra-oil was given. He steadily improved, and at present there remained only some symptoms in the hands. Leprosy was only moderately contagious, and the author knew of no instance of its gaining a foothold in a refined community; he therefore regarded confinement as unnecessary.

Dr. Fuller had seen several hundred lepers at Havana, and said the disease was regarded as contagious, but only slightly, and they were not very strictly confined.

Dr. Moore had been in the West Indies, and could testify to the buoyancy of feeling among the lepers there. He did not think that want of sympathy or mental depression had anything to do in preventing a cure. It was well known that there often occurred intervals when the disease was not progressive. There were instances in which it had been known to be inherited, although it might pass over a generation or more.

Dr. J. C. Peters had seen persons suffering from leprosy in Havana, and they were generally indifferent to their condition.

Dr. D. B. Delavan had visited the institution for lepers in Norway, where there were now only about seventeen hundred, the number having been reduced from over three thousand. They usually came from among the lowest classes. They were not under very great restrictions. He expressed surprise at the position taken by the author of the paper, but he would be glad if his views regarding the curability of the disease might be fulfilled.

Dr. Piffard said that where many patients suffering from leprosy were found the treatment was practically *nil*. The few patients whom he had treated had improved under the use of nux vomica and chaulmoogra-oil. The system became intolerant to one drug if taken for some time, and the two should, therefore, be alternated.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of September 23, 1885.

The President, Dr. John A. Wyeth, in the Chair.

Recurrent Epithelioma of the Penis.—Dr. W. Perry Watson showed a portion of a penis and the patient from whom it had been removed, a laboring man, forty-nine years of age, of good family history, and without any history of specific disease. His health had always been good. Phimosis had existed, which caused marked "ballooning" of the foreskin during urination. In 1865, while he was sitting at table, a fork was thrown at him, and one tine pierced the dorsum of the glans penis. There was considerable bleeding, but a physician was not called. Soon afterward he was admitted into Bellevue Hospital, where, according to his statement, Dr. Hamilton amputated a portion of the foreskin which was said to be indurated. No portion of the head of the penis was removed. The speaker thought it probable that the induration referred to by the patient was a blood-clot. He had no further trouble for about six months, when a wart-like growth developed near the frænum. This grew, and, being constantly irritated, was removed six months later. Six months afterward an ulcerative process set in at the base of the wart-like growth, which increased in dimensions, and for a year before the speaker saw the patient, which was two years ago, gave rise to considerable hæmorrhage. Dr. Watson advised amputation, and the circular operation was done, the urethra being slit up and stitched to the skin. The man had been well since, no tendency to a return of the disease being manifest. The inguinal glands had at no time been enlarged. The epitrochlear glands were slightly enlarged.

The President had seen four cases of epithelioma of the penis during the past eighteen months, in three of which he had performed amputation, and in all there had been phimosis. He had conversed with several surgeons on the subject, and had not heard of a single case of carcinoma of the penis in which there had not been phimosis. This was certainly one other indication for circumcision.

A Vermiform Appendix of Unusual Length and Attachment.—Dr. Louis Waldstein presented a vermiform appendix 16 ctm. long, which he found in a cadaver at the German Hospital. It reached upward to the hepatic flexure of the colon, to which it was attached. Probably there had been slight local peritonitis and displacement of the colon downward, during which the adhesion was formed. The colon afterward resumed its normal position, carrying the appendix with it.

Biliary and Renal Calculi.—Dr. Waldstein also presented a urinary calculus, composed of urates, which was interesting in connection with the history. Mr. S. sent for him in April last, suffering from pain in the abdomen, the greatest tenderness on pressure being over and just to the right of the epigastrium. The pain radiated over the entire abdomen. There was slight icterus of the conjunctivæ and integument. The diagnosis of biliary calculus was made. The patient improved under the use of Carlsbad water. Large numbers of concretions were found in the fæces. Subsequently the speaker was called to visit the patient for an attack of pain which commenced in the right lumbar region, extended downward along the course of the ureter and right thigh, and was diffused over the abdomen. The patient said that when micturating he had a peculiar sensation at the glans penis and a tingling of the fingers of both hands, also some dizziness, and occasionally saw *mouches volantes*. The diagnosis of urinary calculus was made, and subsequently was confirmed by the passage of the calculus presented. An interesting fact in the case was that during eleven or twelve years the patient had had digestive derangement, and finally, as was apt to occur, biliary calculi developed, and also renal calculi.

The President referred to a largely distended vermiform appendix which he had seen while in Bellevue Hospital, but he had never seen one so long as that presented by Dr. Waldstein.

MEDICAL SOCIETY OF VIRGINIA.

Sixteenth Annual Meeting, held at Alleghany Springs, Tuesday, Wednesday, and Thursday, September 15, 16, and 17, 1885.

Dr. Bedford Brown in the Chair.

(*Concluded from page 419.*)

Dyspepsia with Neurasthenia and Somnolence.—Dr. M. L. James, of Richmond, read a paper on this subject. He referred to the fact that, although this morbid association was a serious inconvenience, and sometimes a grave disability, it had not in this particular association received very much of attention in the books. While it very often resulted from the excesses of dissipation in the various forms, it was yet more frequent in the best types of manhood and womanhood, those whose only intemperance was excessive thought and exhausting labors of love, and for that reason especially commended itself to the consideration of men of science and physicians from kindred sympathies. He referred to the fact that indigestion was one of the most frequent causes of neurasthenia, from its combined influences in impairing nutrition and producing a certain species of shock on the nervous system, and that in its treatment it should be remembered that these morbid conditions reacted upon each other. While dyspepsia produced neurasthenia, neurasthenia, on the other hand, was liable greatly to intensify dyspepsia.

He indicated that the judicious treatment of this condition demanded what might be described as training, in which the correction of each of these conditions might be made to contribute to the relief of the morbid condition in the other; that digestion was better performed by securing the utmost integrity of the innervating forces, and the asthenia of the nervous forces was greatly diminished by removing the disorders of digestion. For that reason he emphasized the importance of securing to the patient an ample amount of undisturbed sleep, to commence the labors of each successive day, and then that the food should be selected with a view to its ease of digestion and its capacity to afford nutrition to the nervous tissues. A period of rest in the recumbent position, accompanied by sleep from a half-hour to two hours previous to dinner (after which the greatest amount of difficulty was usually experienced), was attended by the best results.

In the matter of medication, while he spoke of the good effect of a judicious use of stimulants, especially such as stimulated the cerebral lobes and averted sleep, such as was found in coffee or its alkaloid, caffeine, that for permanent restoration those agents which were more decidedly tonic, such as quinine, strychnine, and phosphorus, or its compounds, or such agents in combination with minute quantities of caffeine, were best calculated to afford remedial benefit. He mentioned the following as one of the formulæ which he had been accustomed to use with the most efficient results:

℞ Quininæ phosphat.,	gr. xvj;
Strychninæ phosphat.,	gr. ⅛;
Acidi phosphorici (50 per cent.),	♏xx;
Caffein. citrat.,	gr. xvj;
Aquæ puræ,	f ʒ vij;
Glycerini puri,	
Spts. vini rectif.,	āā f ʒ ss.;
Tr. cardamomi co.,	f ʒ j.

Misc. secundum artem.

One or two teaspoonfuls immediately before or after breakfast or dinner, to be repeated, when necessary, every hour or two till the nervous depression was relieved, or every half-hour till one or two doses were taken if this depression was heavy.

He stated that where digestion was impaired to that degree that food in the ordinary form was not tolerated and digested, he advocated the use of concentrated animal preparations in a fluid form, and of foods predigested by the use of pepsin and pancreatin; and where this amount of difficulty was so extreme that they could not be administered by the stomach they ought to be administered through the rectum.

Report on Advances in Hygiene and Public Health.—Dr. Edwards announced the sudden death of the Reporter, Dr. William H. Coggeshall, of Richmond, on September 7th—just after he had finished his paper. By unanimous vote, Dr. Edwards read the paper, the title of which was:

The Recent Plymouth, Pa., Epidemic and the Lessons it teaches.—A full account of the epidemic was given and deductions were made, based upon an analysis of its history.

Inhumation and Cremation was the title of a paper by Dr. J. E. Chancellor, who spoke of the principal methods of disposing of the dead. The major portion of the paper was devoted to the subject of inhumation and its evils, many authorities being cited, and the testimony of scientists and medical men of the East who had made it a subject of close investigation.

Report on Ophthalmology and Otology.—Dr. Phillip Taylor, of Richmond, read a paper in which mention was made of the practical benefits to be derived from the use of jequirity in trachoma with or without pannus. He insisted upon the fact that chronic purulent conjunctivitis should not be present when jequirity was used. The late theory relative to the transmission of sympathetic ophthalmia—viz., by means of the inter-vaginal lymph-spaces of the optic nerve—was given, and conclusions concerning septic poison being conveyed by the ciliary nerves from the diseased or injured eye to the unimpaired organ—the once popular theory—were rendered. Cocaine received notice as one of the most important strides that had been made in ophthalmology for many years. Its uses and effects were dilated upon. Numerous operations were referred to that had been brought before the profession during the past year, notably one for pterygium by Dr. Prince, of Illinois, another for evisceration of the eyeball as a substitute for enucleation, also one for the transplantation of the cornea. He referred to the danger of performing the operation for internal strabismus in the young and making the correction absolute, and pointed out the fact that, as maturity came on, insufficiency was quite apt to follow, causing external squint.

In otology, some recent preparations for purulent ear troubles were discussed, especially peroxide of hydrogen. New-style Eustachian catheters and the method of using bougies for dilating the Eustachian tube were approved. The connection between diseases of the teeth and those of the ear was referred to, and statistics were rendered showing that sympathy existed between these parts.

Practical Remarks and Suggestions in regard to Diseases of the Ear, Throat, and Nose, with Reports of a Few Cases.—Dr. Joseph A. White, of Richmond, presented a paper on this subject. In speaking of the disastrous consequences of neglected middle-ear catarrh, he remarked that neglected suppurative inflammation had resulted fatally. Pain should be overcome by local leeching, warm applications, the use of twenty-per-cent. solution of cocaine hydrochlorate with atropine in the ear, and anodynes internally. Cocaine did anæsthetize the drum-membrane. Pilocarpine hydrochlorate and calcium sulphide should be administered during the exudative stage, but caution should be exercised in using pilocarpine during the aural troubles following any of the exanthemata lest the heart be paralyzed. If pain persisted and the drum-head bulged, the posterior-inferior quadrant should be opened, and, by aid of the air-bag, the tympanum evacuated. Then the ear should be gently and frequently syringed with carbolated or borated solutions of sodium bicarbonate, and the Eustachian tube kept free by the daily use of Politzer's air-bag. If pain continued, the cocaine solutions should be continued, but the atropine left off, as the latter was dangerous when the drum-head was opened. Powdered boric acid might also be dusted over the drum once or twice a day. Mastoid and diseases of the brain often occurred from neglected middle-ear complaints; permanent deafness was common. Especially during the course of scarlet fever, the earliest signs of ear trouble should receive close attention. Leeching and the use of calcium sulphide would often avert threatening mastoid complications. If there was redness or pain on pressure over the mastoid process, freely incise to the bone, and even trephine the bone if pain continued.

Dr. White next referred to the influence of menstruation at puberty and at the menopause upon ear diseases. Impaired hearing due to adhesive middle-ear catarrh was very common about the climacteric period. He cited the case of otorrhœa which began at puberty and yielded readily to treatment, but recurred at each menstrual period until finally the menstrual irregularity was relieved, when the otorrhœa also ceased.

As to syringing the ear, be careful, he said, not to use too much force in removing impacted wax, foreign bodies, etc. Dizziness, syncope, violent pain, followed by suppurative inflammation and deafness, had resulted from too forcible syringing. To remove impacted wax, first partially dissolve it by

frequent applications of warm solutions of sodium bicarbonate in glycerin and water, and then very gentle syringing would remove the mass. When required to loosen a lump of wax or such a thing with forceps or probe, we should not attempt to do it without good illumination from a head-mirror.

Follicular amygdalitis and catarrhal diphtheria were often confounded. In diphtheria, in addition to the fever, occasional nausea, pain in the throat which generally began on the third day, and patchy exudation on the swollen tonsil, as we had in follicular amygdalitis, the exudation extended over the mucous membrane of adjacent structures. Guaiacum acted almost as a specific in follicular amygdalitis, which supported the belief that rheumatics were most liable to it. If recurrent attacks became common, or if the tonsil became so hypertrophied as to affect nasal respiration or impair articulation, he advised the removal of the enlarged tonsil. The only risk was hæmorrhage, and that usually was but slight. The rule should be to remove anything that interfered with nose-breathing or rendered mouth-breathing necessary. Interference with nasal breathing caused deafness, tinnitus aurium, etc., and the reflex phenomena, such as reflex cough, sick headache, asthma, and hay fever. The paper concluded with reports of two typical cases of hay fever cured by the use of the galvano-cautery applied to the sensitive points of the nasal mucous membrane.

Two Cases of Tracheotomy — One for Lupus of the Larynx, and One for Diphtheria—were reported by Dr. Charles M. Shields, of Richmond. He had found mention in the text-books of about a dozen cases only. The case now reported was that of a retired doctor, about fifty-five years old. He had had hoarseness and pain while swallowing for more than a year. Now he could speak only in a hoarse whisper, and he had dyspnœa. The laryngoscope revealed general redness and congestion, with so much swelling of the right vocal cord and ventricular band as to make them indistinguishable. This growth was covered with small, pale, fleshy tubercles, having superficial ulcerations between them. The patient never had syphilis, nor were there any signs of phthisis, nor was cancer hereditary in the family. These usual causes of laryngeal growths were therefore excluded. The diagnosis of lupus was strengthened by the appearance of two or three small, suspicious ulcerated growths upon his face and arm which would not heal until excised, and which were probably skin manifestations. At first he took iodide of potassium, and afterward arsenic, and, locally, iodoform and bismuth; but the lupus progressed until seven months after the patient presented himself, when the ulceration and swelling occluded the larynx. Both sides of the larynx were immensely swollen and covered with the pale elevations and ulcerations, and no glottic aperture could be seen. Tracheotomy was performed without chloroform, but it was a tedious operation because of his short, thick neck and the pushing down of the trachea by the enlarged larynx, leaving very little space for the incision; an unusually long cannula had to be used. Great relief followed the operation, and he soon learned to remove, clean, and replace the entire tube without difficulty. He was doing well during the next summer.

Dr. Shields also reported a successful tracheotomy for laryngeal diphtheria in a child three years old. After the fifth day the membrane in the larynx increased so rapidly as to threaten death by suffocation. Iron, quinine, and large quantities had been used. Vapor of lime filled the room. Tracheotomy was not consented to by the parents until the sternum was drawn in and the patient was cyanosed and thought to be dying. The tracheotomy-tube was introduced as soon as the incision was made, but all appearance of breathing stopped. Artificial respiration was kept up and the tube withdrawn again, when, with forceps, a membrane, cast upon the trachea, two inches long, was removed. The cannula was again put back, and, artificial respiration being continued, the child finally began to breathe. She did well for two days, when difficult breathing set in, and she coughed up through the trachea another cast. Diphtheritic membrane covered the edges of the wound. No air passed through the larynx for nearly a week, and the tube had to be kept in for three weeks before she could breathe comfortably through the natural channel. She made a good recovery.

Infanticide was the title of a paper forwarded by Dr. Charles R. Cullen, of Henrico County, who was unable to attend. The writer did not follow the usual routine found in the text-books on medico-legal jurisprudence, but merely sought to direct attention to the weakness of Virginia laws on the subject. Dr. William H. Taylor, Coroner of Richmond City for about thirteen years, furnished statistics of 139 persons tried for infanticide during his term of office—43 whites and 96 negroes. Of the total number, not a conviction followed. The laws of England and Scotland had succeeded better. Of 68 trials for infanticide in London, 53 convictions followed. In New York and Pennsylvania the laws were much more certain of securing convictions than in Virginia. The very harshness of the Virginia laws caused them to fail of good results. Dr. Cullen reported two cases of trials for infanticides which had come under his attention, showing the weakness of the Virginia laws, and he called on the society to aid in reframing the State laws relating to infanticide.

A Plea for Tracheotomy in Croup.—A volunteer paper with this title was read by Dr. L. Ashton, of Falmouth. He said that the good that was to result from the timely performance of tracheotomy was so great that it should be placed among the minor surgical operations. This classification would materially help to popularize it and take from it that dread that parents so often felt regarding it. The operation in itself was comparatively free from danger, but was a delicate one, requiring coolness and caution, and, when performed hurriedly, was too often made difficult and dangerous. The operation not being dangerous in itself, nothing connected with its mere performance should influence the time when it was to be resorted to. As soon, he said, as it was decided that a positive mechanical obstruction to the entrance of air into the lungs existed, the operation should be done, before such secondary complications as broncho-pneumonia, œdema of the lungs, prostration of nervous energy, etc., occurred. In the majority of cases of croup death resulted from want of oyxgen in the blood. It should be performed in all cases where the croup was progressive and unaffected by medical treatment. In a number of cases the extension of croup was arrested by tracheotomy. The admission of air into the lungs through an artificial opening in the windpipe secured entire rest for the diseased larynx, and this led to a suspension of diseased action there. The diphtheritic process, clinically speaking, stopped at the level of the vocal cords much oftener than was commonly supposed. When the disease involved the trachea, it was by propagation from the larynx, and not by a simultaneous attack on the larynx, trachea, and bronchi; and this extension downward was generally prevented by early tracheotomy. Since the operation alleviated suffering, mitigated the symptoms, obviated secondary complications, and did not add one element of danger to the original disease, there ought to be no delay in its performance. Many children had even been brought to life again by it, with the aid of artificial respiration.

Psychological Aspects of Suicide.—During the night session Dr. J. S. Conrad, Superintendent of Matley Hill Sanitarium, near Baltimore, Md., by invitation read a paper on this subject, and made the following conclusions:

1. Suicide increased with the advance of civilization, and was but little known in the savage state of men.

2. The act was an intelligent act (?), done with a full consciousness of the act, as shown by the method of execution, whether by the sane or insane.

3. That suicide was done always for the purpose of escaping an evil, and for the benefit of the *felo-de-se*, whether by sane or insane.

4. That it was a voluntary act (?), whether by sane or insane.

5. That it was an emotional act, whether by sane or insane, however deliberately planned and executed, since deliberation entered into the mind of both mental states.

6. That delusions were not essential to the distinction as to the sanity or insanity of the suicide, since authorities affirmed that delusions were not essential to the proof of insanity.

7. That suicide was rare in the first class—insanity (by Maudsley), viz., intellectual or ideational insanity—but did occur in the vast majority of the second class, or affective or emotional forms of insanity.

8. Query: Was suicide an intellectual act notwithstanding the intelligence exercised in its execution? Or was it an emotional act *per se*, since we had seen that the emotional part of mind dominated the ideational centers and perverted the intellect into becoming its humble servant?

9. Did moral depravity satisfactorily account for it, when we had seen that moral depravity was a factor with both the sane and the insane?

10. That, in doubtful cases of the sanity or insanity of the *felo-de-se*, very great caution was necessary in making up a just judgment as to the one or the other.

Irritable Rectum.—Dr. Archer Atkinson, of Baltimore, present by invitation, read a brief paper on this subject, in which he called attention to the various causes for this condition. He also reported a case in which he ligated the artery of a large bleeding hæmorrhoidal tumor.

Gunshot Wound of the Hand.—Dr. William G. Eggleston, of Chicago, reported a case of this injury. C. H. G., a physician, aged thirty-three years, received an extensive lacerated wound of the left hand, in February, 1885, while attempting to remove the cap from a loaded shell. The cartridge exploded, and the entire charge of shot, so far as was known, passed through the hand. The resulting wound extended, on the palmar side, from a point immediately anterior to the normal situation of the deep palmar arch, between the metacarpal bones of the middle and third fingers, tearing the hand completely open, thence to the webbed junction of these fingers, tearing the flesh from the first phalanx of the third finger, save a small portion on the dorsal aspect, and breaking the first phalanx of this finger and the metacarpal bones of the third and little fingers about the middle third.

The wound was thoroughly cleansed with hot water, the clots were removed, flaxen sutures put in place, compresses applied over the palmar and dorsal wounds, and the whole metacarpal portion of the hand was bandaged rather tightly with short bandages, so that they could be easily removed in case of hæmorrhage. The middle finger was used as a splint to the broken third finger. Turpentine was then injected into the wound, and the bandages were thoroughly soaked with it. Subsequently a drainage-tube was put in, and a weak bichloride solution used. On September 10th, seven months after the receipt of the injury, the patient reported that the third finger was practically useless, but that he could do all he wished with the hand; the grip was good, "the stiff finger seldom getting in the way."

Miscellany.

The Report of the Meeting of the Committee on the International Medical Congress.—The "Medical News," of Philadelphia, publishes the following letter from Dr. R. A. Kinloch, of Charleston, S. C.:

"*To the Editor of the Medical News:*

"Sir: The following letter was addressed by me to the secretary of the Committee on the International Medical Congress:

'Charleston, *September 16, 1885.*

'To Dr. John V. Shoemaker,

'*Secretary of the Committee of Arrangements for the International Medical Congress.*

'Dear Sir: In the "Journal of the American Medical Association" for September 12th there is a publication, under your signature as secretary, of what is styled a "Report of the Committee appointed to arrange for the meeting of the International Medical Congress in America in 1887." As a member of the Committee of Arrangements, present during the session of the committee held in New York city on the 3d and 4th of September, I am not aware that you were instructed or authorized to make any other report than such a one as naturally pertained to your duties as secretary. The correct and full report of the minutes of the meetings of the committee it is most surely your duty to prepare, and the publication of such minutes, unless specially interdicted by vote of the committee, seems to me to have been in order. Your "report," as published, is not the minutes of the meeting, nor does it fully or fairly represent these, as far, at least, as relates to the meeting in New York. As a member of the committee I think it due to the committee, and to the profession of our country, that the full action of the committee, which carries with it the animus or real intention which determined its work, should see the light of day. You will therefore pardon me if I appear intrusive when I ask you to inform me if it is your intention to publish a detailed report of the minutes of the late meeting of the committee, held in New York, on the 3d and 4th of September.

'Very respectfully, R. A. Kinloch,

'*Member of the Committee from South Carolina.*'

"This letter was forwarded as far back as the 16th of September, but has failed to elicit a reply. I am, therefore, forced to conclude that I shall not have the courtesy of a reply, and that there will appear no official report of the minutes of the meetings of the Committee on the International Congress, notwithstanding the interest manifested in this matter by the profession. As a member of the committee, however humble, I am not ashamed of any views I have expressed, or of any action I have taken. Nor do I desire to bear the sins, either of omission or commission, or to claim the fruits of the good work that may be the outcome of this body.

"I accepted a position on the enlarged committee created by the action of the American Medical Association at its late meeting in New Orleans, not because I approved of the action of the association in its mode of dealing with the work of the original Committee of Eight, but because I recognized the obligation to serve the association, and indulged the hope of sustaining a spirit of harmony, which I feared might be interrupted by the diversity of opinions coming of a too ponderous committee of arrangements.

"That the committee could best discuss the respective merits of men suggested for filling important offices in the Congress by sitting with closed doors, was an argument of some force; but it will scarcely be urged by scientific men that the shortcomings of the body, the conduct and ruling of its officers, the time of its discussions, the policy of its actions, the views and the animus of its individual members, should be guarded in the same way, and known only to unwritten history. Why, then, I ask, this suppression of this much of the proceedings of the meetings? And by what authority does the secretary of the body undertake to report in the way that he has done? As I was absent from the meeting for a brief period prior to its adjournment, it is possible that the committee may have instructed the secretary as to his

course of action. If so, I can only at this late date raise my voice in condemnation of such a policy.

"All the acts of the committee were of course the result of a majority vote, and, so far as it has worked for the supposed advantage of the Congress, I prefer to say nothing. I trust that its action will prove satisfactory. But, while majorities rule, minorities have certain rights, and among these is the right to be put upon record. As an independent member of the committee, I do not intend that my rights shall in all particulars be ignored. The verdict of a noble profession is something that I hold of inestimable value; the approval or disapproval of a court so constituted I am willing to accept, provided such is based upon my individual merits or demands. There was with me during all my connection with the committee the proud desire to promote harmonious action, and thus save the American Medical Association and the profession of our common country from dissensions which threatened their well-being, if not the vital interests of both, and which already have, in part, subjected us to the censure, if not the ridicule, of our foreign brethren.

"My first effort was at the informal meeting of the new members of the committee at New Orleans, when I introduced the following resolution, after there had been presented several propositions, all of which, as seemed to me, were calculated to give some offense to the original Committee of Eight.

"'*Resolved*, That the temporary officers of this meeting be instructed to correspond with the original committee, expressing our desire to meet them at such time and place as may be agreed upon by the majority of the entire committee.'

"The original committee had worked laboriously and deserved something of the association. If they had committed errors, they could not escape criticism; but with members of a common brotherhood, looking to scientific progress, criticism need not give offense. No proper-feeling brother desired to add to the mortification or irritation which naturally attached to the members of the original committee, when there were appointed additional members to their body, for the purpose of reviewing their work. The object of my resolution then was to try at the outset to establish friendly relations with the original body. The new members were merely *material added to this*. The original committee was the fully organized body. It had not been abrogated, nor was its organization changed by the recent action of the association. A cautious word from the temporary officers elected by the new members, if these officers were capable of appreciating the spirit of my resolution, was really the first and surest way of harmonizing the new with the old members of the committee.

"Dr. Flint and Dr. Billings were the officers of the Committee of Eight. They were also, now, the officers of the enlarged committee, until that committee should meet and decide to supplant them. It rested, then, with these gentlemen to call the committee together; *the duty pertained to none others*.

"Some confusion arose in regard to the function of the committee as enlarged, and as to the attitude of the original committee to the association. The members of the original committee naturally desired time for conference and careful conclusion. This should have been accorded them. But, unfortunately, the temporary officers of the meeting at New Orleans incorrectly estimated their position and failed to perceive that harmony was necessary for professional unity, and unity essential to the scientific interests of the Congress. The function of these temporary officers had ceased after they had carried out the instructions given them by my resolution. And yet they magnified their recent position, forgot the spirit of their instructions, ignored the existence of the president and secretary-general of the committee, transferred the headquarters of the committee from Washington to Philadelphia, called for the vote of all the members of the committee, as to time and place of meeting, and resolved to meet at Chicago on the 24th of June. Strange to say, it does not seem to have occurred at that time to any of the members of the committee, besides myself, that these temporary officers of the New Orleans meeting had committed a bold and unjustifiable act. This was painfully evident to me, however, for I saw at once that the letter and spirit of my resolution had been trampled under foot, and I lost hope in the success of the Congress.

"The call for the Chicago meeting, made in the name, or under the authority, of my resolution, seemed to be accepted by the committee as right and proper. I alone protested and refused to vote. My protest was sent to the 'Association Journal,' but reached the editor too late, as he informed me, for the issue which immediately preceded the time of meeting of the committee. As a final effort, I wrote an earnest letter to Dr. Cole and Dr. Shoemaker, and insisted that my views should be presented to the meeting in the event of my failing to be present. The meeting was held at the time specified, *but my letter or views were not mentioned*.

"The result of the Chicago meeting is known to the profession. I was unavoidably absent, and subsequently shared only in the general regret that the character of the work done necessitated its reconsideration. The meeting at New York was called partly for this purpose. I was present, and at the earliest moment I claimed the privilege of having recorded upon the minutes the letter which I had written to the 'Association Journal,' and which explained fully my views as to the unjustifiable action of the temporary officers in calling the Chicago meeting. I also made the public statement as to the failure of these officers to bring my letter before the committee at Chicago. Through the failure of the secretary to publish the minutes of the New York meeting my views were again suppressed, and hence the unpleasant necessity of having now to justify my action. It is due to the officers of the meeting to say that they disclaimed any intention of purposely suppressing my letter at Chicago, but, at the same time, they offered no very satisfactory reason for their singular omission.

"The next matter which duty to myself compels me to notice has reference to the alteration of the rule, as adopted at Chicago, determining the American membership of the Congress. This rule had been fixed, as was claimed, *in obedience to the voice of the American Medical Association*, so as to restrict the membership on ethical grounds. The determination of a few adroit members of the committee was now to undo what had been done, and in their own peculiar way. By management more suitable for a political than a professional or scientific body, and which I will not now comment upon, the rule, as prepared for presentation to the committee, which it was claimed opened the Congress to all members of the regular profession, was finally brought before the body. I asked the gentleman who had introduced the subject whether, under the proposed rule, all members of the Congress would be alike eligible for office, and whether he would favor the election of any member of the profession simply upon his merits, or whether there was not a mental reservation upon the part of those suggesting the change by which, upon ethical grounds, certain members would be members merely, and debarred from holding office.

"The answer came that in accordance with the 'resolution' of the American Medical Association certain parties must be refused high position. I asked for the reading of the 'resolution' referred to. I wanted to know whether the association had ever drawn any such fine distinction, opening the membership to all, but restricting the distribution of honors. It turned out that there was no such resolution ever adopted by the association. I then maintained that if the association and its implied sentiment were to guide the committee upon this occasion, it was more consistent to hold on to the Chicago rule than to accept the amendment as now proposed. I offered to support the amendment with all my heart if this was honestly offered, and if the mover would amend it further by stating that all members were equally eligible for office, or if he would agree to show that, practically, all were eligible by voting for men on their merit and regardless of ethical standing. If this was declined, I insisted I could not vote for the amendment, for I would not pretend to offer bread and give a stone. My proposition was not accepted, but the new rule was adopted without my vote, and *all in the name of the association*.

"One other point deeply interested me, and determined my rejection of office. It was well known that the rule, as adopted at Chicago, which restricted the membership of the Congress upon ethical grounds, had occasioned the resignation or withdrawal of many of the best and strongest men in the profession, regardless of their views on the code question. A conciliatory spirit on the part of the committee, as now newly constituted, was of supreme importance, for we could ill afford to do without so many of the good minds of the country. Under the resolution of the association, the committee had power to fill all vacan-

cies occurring in its owu body, aud to appoint officers to the Congress. This was regarded as implying the right to accept resignations from positions which had been previously filled by the original Committee of Eight, or by the present enlarged committee at its meeting in Chicago. The work of filling vacancies was being pressed on, *when the committee had no knowledge of resignations except the mere verbal report of the secretary.* The idea seemed not to have occurred to any one that all letters of resignation should be read before the committee, or that courtesy and justice to the parties sending such letters demanded such reading. It looked as if the officers of the committee, and not the committee itself, were, to use a trite expression, 'running the machine.' I desired, naturally enough I thought, to know the reasons for the resignations which had beeu sent in to the secretary, and therefore asked for the reading of the letters. We were surprised to learn from the secretary that the letters had been left in Philadelphia, and, besides, that they were so numerous that there would scarcely be time for their reading. I nevertheless urged that the telegraph should be used to insure the letters' reaching us in due time. The secretary finally arranged to send a special messenger for the papers, and they arrived in time for the second days' session. I now again called for the reading of the letters. They were, under resolutious offered in plea of press of business, twice put upon the table to await convenience. But at last I succeeded in having a few letters read. I heard enough to conclude that if the obstructions to membership and to the honors of the Congress were really removed, and a proper spirit of conciliation evidenced by the committee, most useful men could yet be saved to the Congress. Meantime the work of filling the so-called vacancies in the most important offices had continued without any questions as to the acceptance of resignations. The spirit of vindictiveness (I regret to have to use the term) under the presumed offense given by the parties who had proposed to withdraw seemed to me to be irrepressible, so I could not consent to occupy the position of vice-president in the Surgical Section which had been assigned me, both by the original committee and the present one. As an unavoidable engagement precluded my presence at the meeting of the committee toward the close of the session, when the list of vice-presidents of the sections was up for consideration, I left with a member of the committee my written reasons for declining office. These were read, but of course suppressed with other portions of the minutes.

"In conclusion, let me state that I think it not unlikely that some of my professional brethren will charge me with egotism, and condemn the course I have pursued in thus publicly announcing personal grievances. This I shall regret, but I apprehend there will be many who will agree with me that personal grievances may be blended or indissolubly connected with the interests of the whole profession. Had I not regarded those which I have here recorded as of that category, I should never have adverted to them.

"One word in relation to the gentlemen constituting the enlarged committee. Many of them are my personal friends. I dispute not the right of individual opinion. I claim no superiority over my brethren, but my own convictions are strong and sincere. There are many of the committee whom I know to be as conservative as I claim to be. I feel grateful to some for the support I received while striving to modify the determined policy of the majority. I intend no offense to the committee as a whole, unless it be an offense to offer the assurance that now and ever I do not mean to allow my individuality to be destroyed.

"R. A. Kinloch,

"*Member of Committee from South Carolina.*

"Charleston, *October 1, 1885.*"

The American Medical Association and the International Medical Congress.—"The more one considers the question," says the "Medical Times and Gazette," of London, "the more fatal do the objections appear to the principle of allowing a pre-existing medical association to play the sole part in organizing an International Congress. No medical organization whose aims are not purely and exclusively scientific can ever be truly representative of medical science. The men who are the real workers in the field of medical research, and who are therefore the only proper representatives of the profession in a scientific meeting like the International Congress, are hardly ever found playing a leading part in associations of a medico-political nature. Quite properly they leave such functions to those of their brethren who have business proclivities and time upon their hands. The latter class may be admirably fitted for the work of conducting a large medical association, but they are not qualified to greet on even terms the medical investigators of the world, and we doubt even if they are competent to decide who are best qualified to give that greeting. Thus there is always the risk, exemplified in the United States just now, of their dragging the political and ethical questions that are nearest to their hearts into competition with purely scientific questions. The ouly safe way of organizing a successful International Congress in any country is to leave it in the hands of the leading scientifie men, who are known and acceptable not only to the hosts of the Congress, but also to its guests. We hope that on some future occasion this principle, which has until now invariably been acted upon, will be formally converted into a standing rule."

Decline the Invitation.—Under this caption the "Medical Record," of New York, says: "The month of grace allowed for the return of the gentlemen who withdrew from the organization of the Ninth International Congress has passed. There are no signs yet of the hoped-for return. The possibility, as suggested by us last week, of affecting in some way the ruinous course of the present committee, is now destroyed by the recent action of the Executive Committee, which has formally assumed dictatorial powers. We think, therefore, that it would be better, for the credit and harmony of the profession, that the acceptance of the invitation to hold the Ninth International Medical Congress in this country be withdrawn."

Excipients for Permanganate-of-Potassium Pills.—Mr. Edgar L. Patch, of Boston ("Pharm. Record"), says that, when he first had occasion to dispense permanganate-of-potassium pills, he chose that excipient nearest at hand which seemed to meet the requirements of making a mass quite readily, and preserving the salt from rapid decomposition. This was resin cerate, and, the permanganate being used in very fine powder, the cerate met the first requirement so well that he persevered in its use after Martindale had suggested the use of kaolin and paraffin, and Proctor that of kaolin and water. He never kept the pills in stock, and argued that their comparatively slow solubility was of advantage in preventing the too powerful local action of the salt. Nevertheless, some of his customers asked if the pills should "cause distress in the stomach?" He also recommended resin cerate to others who had stray calls for the pills, and who found difficulty in obtaining kaolin. Inquiry revealed the fact that at that time few wholesalers handled kaolin, and that some who sold "China clay" informed their customers that they knew nothing of kaolin.

"*Pure* kaolin," he continues, "is a white elay, a hydrated silicate of aluminium, having the formula $H_2Al_2Si_2O8+H_2O$. Comiug largely from China, where it is found near the Kauling Mountains, it derives its name *Kaolin* from the locality mentioned. It is also found in France, Saxony, England, and various localities in America." Obtained from three different localities, its composition varies somewhat, ferric oxide, lime, magnesia, alkalies, and water being present in varying proportions. Hence samples differ in plasticity when mixed with water, and the many statements regarding its value as an excipient may be harmonized. After experimenting with the various excipients that have been suggested, he recommends one of the following: 1. Resin cerate, in proportion varied according to the size of the mass, from 15 to 20 per cent. of the finely powdered permanganate used. Five grains will make a mass with 25 grains of the salt; 15 grains will make a mass with 100 grains of salt. 2. One part of permanganate, $1\frac{1}{2}$ parts of kaolin, and water, q. s." (Proctor.) The amount of water required will vary from $\frac{1}{2}$ to $\frac{3}{4}$ of a part. 3. Permanganate, 2 parts; kaolin, 1 part; and petrolatum, q. s. The amount of petrolatum required depends upon its consistence. He uses ouly $\frac{1}{2}$ of a part; as, permanganate, 24 grains; kaolin, 12 grains; petrolatum, 4 grains, makes a mass somewhat more plastic than No. 1, and decidedly more so than No. 2, which has to be handled skillfully to get satisfactory results. Of the three masses, No. 2, with kaolin and water, disintegrates rapidly in contact with water; No. 3 more slowly; and No. 1 the slowest of all. Of their permanence he is unable to speak from personal observation, but it has been stated by Mr. George Smith ("Pharm. Journal," 1884)

that masses made with kaolin and paraffin lose from 50 to 70 per cent. by decomposition after six months' time. In view of this the pills should be freshly made, and the pharmacist may work by any of the three formulas suggested that best suits the case in hand.

Active Principles in Pharmacy.—Dr. R. G. Eccles, of Brooklyn, contributes to the "Pharmaceutical Record" an important article on "Infected Solutions," beginning with the following remarks:

"Aromatic waters, dilute solutions of phosphoric, citric, tartaric, oxalic, and other acids and their salts, as well as most alkaloidal solutions, encourage the growth of a variety of aquatic cryptogamous plants, whose polluting presence renders them unfit for use. They are unwelcome visitors everywhere, but in the last-mentioned places they are a great commercial misfortune, so that their suppression is a subject of growing interest. That it will continue so to grow is apparent from the trend of medical science. Every advance made by therapeutics discredits the use of tinctures, infusions, decoctions, extracts, etc., as at present indiscriminately prescribed.

"1. Because all medication is found to be an injury to the system, and on no account to be indulged in except to suppress a greater evil.

"2. Because these preparations almost invariably contain some drug not needed by the patient.

"3. Because they often contain drugs positively contra-indicated by the disease, combined with such as are pressingly necessary for the same.

"4. Because the strength of such preparations is never twice alike, and it is merely an accidental guess when the proper dose is given.

"5. Because the physiological effects of many drugs are found to border upon the toxic. If too much is given the patient is injured; if too little, he is insufficiently or not at all benefited.

"This is why the alkaloids of cinchona have, to so great an extent, displaced the older forms of administration. This is why those of belladonna, nux vomica, and opium are pressing forward in the same direction. This is partially why cocaine has been found so useful at a time when coca was about to be thrown aside as of little value. The day of active principles in pharmacy is only beginning. Every year must add to their popularity, and discredit to a great extent all that now take their places. Definite solutions like Magendie's will ere long be in daily call, and these will represent all the virtues of the vegetable world. There will then be no stimulating with alcohol when a depressant is desirable, nor constipating with tannin when heart pressure only is needed. Hypodermic medication points the way we are bound to travel, and in this method of practice all the old drug preparations are worse than useless. All the changes here foreshadowed will not come in our day. Enough, however, will come to make the loss from infection become an item of financial importance. Cocaine at ten cents a grain and eserine at twenty-five are worth saving. If we could calculate the loss upon the former from this cause during the past year it would no doubt amount to a snug sum."

The Health of Michigan.—Reports to the State Board of Health, tabulated by the secretary, Dr. Henry B. Baker, show that during the month of September diphtheria was noted at fifty-six places, scarlet fever at forty-two, typhoid fever at forty-nine, and measles at five. As compared with the averages for the corresponding month in the years 1879–1885, intermittent fever, remittent fever, dysentery, typho-malarial fever, cholera infantum, cholera morbus, diarrhœa, pulmonary consumption, and typhoid fever showed a diminished prevalence.

A New Journal of Therapeutics.—"Clinical Notes on the Local Treatment of Disease; a Record of Practical Therapeutics," is the title of a new journal, edited and published by Dr. Charles L. Mitchell, of Philadelphia. The first number, dated October, 1885, contains twenty pages of reading matter, all on subjects of practical interest. Like Dr. Squibb's "Ephemeris," "Clinical Notes" is designed for gratuitous circulation, and the publisher does not bind himself to issue it at stated periods, but only as material and circumstances may permit. From Dr. Mitchell's well-known interest in therapeutical appliances, it is to be expected that the journal will be one of value.

A Companion-Piece to "Per Orem."—The "Centralblatt für Gynäkologie" heads one of its abstracts "Anteflexio uteri mit Stenosis *ossis* interni," which can mean nothing else than anteflexion of the uterus with stenosis of the internal *bone!*

THERAPEUTICAL NOTES.

Digitalis as a Cardiac Stimulant in Children.—At a recent meeting of the New York Obstetrical Society a discussion took place on the treatment of bronchitis in children. Speaking on the question of stimulation, and limiting his remarks to cases of simple catarrhal bronchitis in children between six months and a year old, Dr. A. Jacobi said that in ordinary cases alcoholic stimulants were not necessary, but that he never omitted the use of such cardiac roborants as digitalis. Like a number of other drugs, digitalis, he said, was borne by children in relatively large doses, and he had found it act better as a cardiac stimulant if given in two or three large doses each day than if given in small doses frequently repeated. For children of the age mentioned he would gave a grain twice a day.

Cocaine in the Treatment of Whooping-Cough.—Dr. Moncorvo, of Rio de Janeiro ("União Med."), who has written forcibly in commendation of the use of resorcin in the treatment of whooping-cough, now recommends hydrochlorate of cocaine as an adjuvant. The throat is to be swabbed with a ten-per-cent. solution of cocaine. In a few minutes the parasiticidal solution of resorcin may be applied to the same parts without provoking either pain, vomiting, or a paroxysm of coughing.

Styptics and Depressants in the Treatment of Hæmoptysis.—Apropos of a recent article on the treatment of hæmoptysis, by Mr. W. H. Kesteven, Dr. Godwin Timms, senior physician to the North London Consumption Hospital, writes to the "Lancet" that, for the last twenty-five years, he has treated hæmoptysis with tartarized antimony, one sixteenth of a grain, in a saline draught, every hour or two. Where the profuseness of the hæmorrhage or the patient's anxiety makes it advisable to produce an immediate effect, forty minims of oil of turpentine are given every two hours, in a wineglassful of water. He adds that this treatment is most successful, except in the rapidly fatal cases in which the hæmorrhage comes from the bursting of a small aneurysm. On the other hand, Mr. F. W. Allwright, of Beaconsfield, writes to the same journal in recommendation of astringents. He can not imagine how depressants can stop bleeding, and says that he would never again try ipecacuanha.

Beef Powder in the Treatment of Simple Ulcer of the Stomach.—Under the inspiration of M. Debove, M. A. L. Pradet has written a work on the treatment of simple ulcer of the stomach, in which, as we learn from a review in the "Union médicale," he recommends the use of a mixture of beef-powder and bicarbonate of sodium. Small doses, he says, should be used for the first two days, but afterward 1,500 grains of beef powder (*poudre de viande*) and 450 grains of bicarbonate of sodium may be given daily to a man, and 1,125 grains of beef powder and 360 grains of the sodium salt to a woman. The treatment should be pursued until complete recovery has taken place, and it is only with extreme carefulness that the patient should be allowed to resume the use of ordinary food.

A Palliative of the Pains of Dyspepsia.—The same journal attributes the following prescription to M. G. Sée:

Tincture of hyoscyamus Tincture of conium	each	150 grains;
Tincture of gentian		75 "
Essence of anise		10 drops.

From ten to thirty drops are to be taken with each meal, as a remedy for the pains of dyspepsia and cancer of the stomach.

Oxygen in the Treatment of Leuchæmia and Pseudo-leuchæmia.—Kirnberger ("Dtsch. med. Wchnschr."; "Union méd.") reports a case in which, after the failure of arsenical treatment, inhalations of oxygen produced a rapid increase of strength, with diminution of the swelling of the spleen, the white globules becoming less numerous, and the red globules regaining their normal proportion. After a few months a relapse took place, but, although the red corpuscles were diminished in number, the white ones were not increased—a condition termed pseudo-leuchæmia. Finally, arsenic having again failed, the inhalations led to a definitive cure.

Original Communications.

CONTAGIOUS CONJUNCTIVITIS; ITS CAUSES, PREVENTION, AND TREATMENT.*

BY JOSEPH A. ANDREWS, M. D.,

MEMBER OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY; OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK, ETC.

THE literature of bacteriology fairly bubbles over with ingenious hypotheses; and yet the germ theory of disease is justly one of the chief principles of modern science, and substantial facts are steadily being brought forward to prove the influence of bacteria as morbific agents. It certainly is true that reports have reached us which would seem to negative the deductions from some of the experiments of prominent workers in this field of investigation; but there has been a great deal of hasty and groundless opposition to these researches. However, the inquiry into this matter is being vigorously pushed by skillful workers in the laboratories of Germany and France, and research of such vast importance to the whole human race deserves the greatest possible encouragement, and should not be regarded alone with the intellectual interest which theoretical inquiry excites.

The views which I shall have the privilege to lay before you this evening are the outcome of a practical inquiry into the cause and prevention of contagious conjunctivitis. I can only regret that the case of successful inoculation of a pure culture of the gonococcus which I made a short time since did not have for its field of operation a healthy human tissue; however, it is for others to decide whether the result obtained be of value or not.

In May, 1882,† Neisser declared that the gonococcus originally described by him in 1879 was the pathological principle of gonorrhœa; that it was the actual contagium of the gonorrhœal affection. That the presence of a micrococcus form is constant in the secretion of gonorrhœa has been confirmed by Bokai, Weiss, Aufrecht, Ehrlich, Brieger, Gaffky, Sattler, Leber, Haab, Hirschberg, Sternberg, and others; but all writers are not agreed that the micrococci they have seen in gonorrhœal pus were those occurring only in gonorrhœa, or the same which are found in all pus which has been exposed to the air, or that they differ in form and size or in other characteristics from the micrococci of other blennorrhœas. Neisser maintains that the "gonococcus" is a specific kind of coccus, which is not alone functionally but morphologically characteristic.

According to its discoverer (Neisser), the gonococcus is comparatively large, flattened on the side which is turned toward its neighbor, somewhat oval, seldom single, almost throughout double. It lies close to its neighbor with only a fine fissure between the two; in shape it is "*semmelförmig.*" It multiplies by division transversely, forming a pair, these dividing at right angles to the first line of division, thus forming a group of four; they never occur in the chain-form; they are found free in the fluid, or more frequently adherent to the pus-corpuscle and epithelium. The arrangement in groups of two and four is constant in gonorrhœal pus, and, although this grouping is sometimes seen in specimens of pus from other sources, the chain-form is the more common in them. Bockhart found the gonococcus group mostly on the pus-cells or their nuclei, never in their interior; Haab, on the contrary, found them within the nuclei.

Eklund* denies that the gonococcus is alone specific for gonorrhœa, because he professes to have found similar organisms in acute and chronic purulent processes in the lungs and intestines, in ulcerative stomatitis, etc. But the bacterium of gonorrhœa seems to possess an ability which all forms which resemble it do not—viz., that of penetrating into the living cell protoplasm and of multiplying in it; but this power is soon exhausted.

In the normal human saliva there are micrococci which resemble those of gonorrhœal pus; but, if there is a morphological resemblance, their functional characteristics are, at least, not the same as those of the gonococci. There is a short, thick bacterium in the vaginal secretion, swelled by coloring agents and looking like a diplococcus. Bumm and Bockhart profess to have found the "semmelförmig" diplococcus in the secretion of the female genitals, in diphtheritie sores, in ulcerative process in the mouth, and in a preparation of the sputum of a patient with whooping-cough. Welander† found Neisser's gonococcus in all cases in which he looked for it—among 129 cases of acute and 15 cases of chronic urethral blennorrhœa; even cases of eight to sixteen months' duration were not excepted.

Neisser twice saw profuse purulent discharge from the urethra of a man which occurred after very frequent catheterization preparatory to lithotrity. The secretion contained abundant evidence of the presence of bacteria, but no gonococci were found.

In my case of successful inoculation of a pure cultivation of gonococcus I proceeded in the following manner: The cultivation medium was serum of the blood of the ox, prepared according to Koch's directions, being heated daily one hour, for six successive days, to 58° C., and thus sterilized and gelatinized by subjecting the serum to a temperature of 65° C. A small quantity of fresh pus from a case of acute urethral gonorrhœa was allowed to drop from the urethra on to the sterilized platinum-wire, and then to drop off the latter, leaving only a thin layer of pus on the wire; the wire, thus charged, was thrust into the firm blood-serum in three or four different places, and the test-tube closed with sterilized cotton-wool; a number of test-tubes were thus planted and placed at once in the incubator, the temperature of which was maintained in different cultivations at 32°–36° C. After about twenty-four hours, further inoculations were made from the first tubes. With the seventh generation I inoculated a human conjunctiva. The case was one of granular

conjunctivitis *in stadio cicatricio* and with dense pannus, but without purulent secretion or any discoverable cocci in the conjunctival secretion. The choice of treatment lay between the use of jequirity and inoculation with gonorrhœal pus. Nothing was concealed from the patient, and he sanctioned the inoculation with full knowledge of what the consequences might be. I had unsuccessfully inoculated so many different animals with cultures of the gonococcus that I hailed with extreme delight this opportunity to make the trial in the case of a human being. Three weeks previous to this operation I had inoculated the same eye with a pure cultivation of the coccus taken from my own saliva, the result having been negative. I prepared the conjunctiva for the reception of the pure cultivation of the gonococcus by washing the conjunctival surface for several days with *pure water*. I then conveyed the cultivation to the conjunctival sac and bound up the eye with a roller bandage and absorbent cotton-wool, due attention having been given to the condition of these things. The result was a perfect picture of gonorrhœal conjunctivitis with abundant evidences of the presence of the gonococcus.

Bockhart * obtained a successful inoculation, from a pure cultivation (gelatin) of the *fourth generation* of the gonococcus, on the sound human urethral mucous membrane. The subject of the experiment was a forty-six-year-old paralytic whose death was expected daily. On the sixth day a typical gonorrhœa was formed, which increased in severity up to the twelfth day, when the patient died. The characteristic gonococci were found in the secretion.

Sternberg's criticism on this case is, that the fourth successive cultivation is not sufficient to insure the exclusion of the original material—"a hypothetical non-living virus"—"when the cultivation is conducted upon a solid substratum."

Sternberg did not succeed in producing urethral gonorrhœa in himself and two others with a pure culture of the gonococcus.

Loeffler and Leistikow † had negative results after inoculation of apes, dogs, and rabbits with a pure growth of the gonococcus.

Krause ‡ cultivated the cocci from ophthalmia neonati on blood-serum, and with the pure cultivation inoculated the cornea, conjunctival sac, and urethra of full-grown rabbits, and adopted the same procedure in the case of young cats, pigeons, and mice; but these experiments, as well as subcutaneous inoculation of rabbits and mice, were without result. Krause then inoculated the conjunctival sac of new-born rabbits (six to ten days old) with the same cultivations (from ophthalmia neonati), and produced a purulent conjunctivitis, which was present twenty-four hours after the transfer, and in the course of the following days became more intense. Three of the rabbits died, on the fifth and seventh days after the inoculation, from other causes; one animal lived for some time; in this one, on the tenth day there had developed a very profuse purulent discharge from the conjunctiva; the pus had the ordinary cheesy character of rabbit's pus, and contained, in addition to bacterial contaminations, numerous cocci which were somewhat smaller than those of Neisser. On the following day there was an abscess of the cornea, which perforated the latter. Krause does not assert that this result should be accepted as conclusive. He maintains that in this case Neisser's gonococcus was the active agent in the infection.

The successful inoculation of the urethras of three medical students with gonococci cultivated by Bokai can not be accepted as conclusive, because of the manner in which the cultivation was conducted.

It appears that animals are not susceptible to the poison of gonorrhœal pus, neither the cocci nor the pus itself being capable of reproducing the disease in them.

What interests us most is whether the gonococcus is the cause of gonorrhœa in the human subject; and when the objection, that the essential agent in the infection is a soluble unorganized substance contained in the pus used for inoculation of the cultivation medium, has been removed by isolation of the coccus, and the disease is induced with it alone, then we have very strong facts to argue from.

Ætiology of Ophthalmia Neonati.—According to von Graefe, all inflammations of the conjunctiva are contagious through the secretion which they furnish—contagious in the sense that this secretion must be conveyed to the conjunctival sac of a healthy eye. The more intense the swelling and discharge from the original diseased mucous membrane, and the more acute the inflammation of the latter at the time of the conveyance, the more active will be the poison. The hypothesis of contagion through the air was admitted by von Graefe, and is still held by some excellent observers; but infection through this source, I feel sure, is quite rare, and, when there seems to be no other source than the atmosphere to fall back upon in a given case of contagious eye-disease, we should still refer to the atmosphere as a probable source of infection with misgivings.

The chief cause of ophthalmia neonati is infection derived from the genitals of the mother, either at the time of birth of the child or a short time afterward, the poison in the latter instance being transferred to the child—healthy at birth—through the medium of the bath-water, but much more probably through sponges, towels, etc.

Credé maintains that a *pure catarrhal secretion* of the genitals does not produce blennorrhœa, but Haussmann * says that the vaginal secretion may be infectious. Zweifel † inoculated normal lochial secretion upon the conjunctiva of the new-born in six cases without producing blennorrhœa even once. I inoculated normal lochial secretion upon the conjunctiva of the new-born in three instances, the result being negative. In spite of these facts, it has been maintained that the normal lochia does give rise to conjunctival blennorrhœa. But there is no positive proof that this is anything more than a mere assertion.

* "Beitrag zur Aetiologie und Pathologie des Harntrippers:" "Vierteljahresschrift f. Dermatologie u. Syphilis," 1883, Heft i, p. 8.

† "Verhandlungen der Gesellschaft der Charité-Aerzte zu Berlin," Sitzung vom 16 Februar, 1882.

* "Archiv f. Gynäkologie," 1881, Bd. xxi, p. 523.

† "Archiv f. Gynäkol.," Bd. xxii, p. 329; see, also, his recent communication on these cases, same Archives, Bd. xxiii, p. 325.

We know that gonorrhœal pus, placed in a healthy human conjunctival sac, gives rise to the same disease with the precision of a physical experiment; therefore the view that normal lochial secretion produces conjunctival blennorrhœa in one person and not in another seems, according to this reasoning, to be untenable.

I believe that the infection occurs some time after the birth of the child much more frequently than is generally supposed, the original source of the infection being the same as in the first instance; and from this original cause many other eyes may be infected by direct conveyance of the poison to them by the mother or nurse. I could cite many instances in my own experience to support this statement. The cases of purulent conjunctivitis which occurred in my service at the Nursery and Child's Hospital (Country Branch) in 1879 originated in this way.

At the Foundling Hospital in St. Petersburg during six years 2,918 cases of ophthalmia neonatorum were observed, and simultaneously 345 wet-nurses of the children were attacked with the same disease.*

Theremin † has recorded a table from the same institution embracing six subsequent years, according to which 476 cases of "blepharo-blennorrhœa" occurred, and the relative frequency of the disease at and after birth is indicated as follows: On the first to the fourth day, fifty-seven cases; from the fourth to the eighth day, one hundred and thirty-four cases; from the eighth to the fourteenth day, ninety-four cases; later, one hundred and ninety-one cases. Olshausen thinks that when the disease occurs after the fourth day the child was infected after birth. Although ophthalmia is infrequent among the better class of patients, it is quite common among the ignorant poor, and the homes of such people are constantly menaced by the danger of a child at the breast, already a victim of the disease in question, infecting the whole family. Haussmann thinks that the purulent secretion from a sore nipple may become a source of infection.

The question has been freely discussed as to whether Neisser's gonococcus is the special bacterium of this disease. Whoever may be interested in reading over the contradictory views on this subject will find an abundance of material in Haussmann's work, "Die Bindehautaffection der Neugeborenen," Stuttgart, 1882. Leopold and Wessel ‡ tell us that, of eighteen mothers whose children were not placed under prophylactic treatment, gonococci were found only in the case of one mother, and, on the third day after the birth of her child, the latter presented the familiar appearances of conjunctival blennorrhœa. No gonococci could be found among the remaining seventeen women, and their children remained free from any inflammation of the eyes. Their article contains many instructive details which it would be quite impracticable to incorporate in the present paper, which has already assumed proportions much greater than I had originally prescribed for it.

* Froebelius, "Medicinische Zeitung Russlands," 1885, Bd. xii, No. 33, p. 257; cited by Haussmann.

† "St. Petersburger med. Zeitschrift," Bd. v, p. 97; cited by Haussmann.

‡ "Archiv f. Gynäkol.," 1884, Bd. xxiv, p. 93.

Haussmann * cites the statistics of Cederskjöld, of Stockholm, according to whom the eyes of the children of mothers with blennorrhœa were diseased in 14·6 per cent., and of the children of mothers free from blennorrhœa only 5·52 per cent. were affected. But the 5·52 per cent., were they not infected by the others?

Granular Conjunctivitis.—At the Ophthalmic Congress in Heidelberg, in 1881, Prof. Sattler announced that he had succeeded in finding in the conjunctiva of granular conjunctivitis micrococci which resembled those of Neisser, and that with a pure cultivation of those cocci he had reproduced the disease in question in a man. Leber confirms Sattler's statement as to the finding of cocci in the tissue of granular conjunctivitis. About thirty years ago Arlt † taught that there was an intimate relationship between granular conjunctivitis and struma, also tuberculosis. This view has been pretty generally abandoned by ophthalmologists of the present time, and Sattler's discovery might dispose us still further to differ with Arlt, but it is very probable that Sattler is in error in this matter. I have searched in vain for any micrococcus form in the tissue of granular conjunctivitis. In a paper published last year ‡ I gave the details of the manner in which I had proceeded in investigating this question. I had examined 1,500 sections taken from 37 cases of trachoma without being able to find any cocci in them. I have since carefully examined five cases of this disease, with the same end in view, but, although I have applied the proper staining agents and the other indispensable aids in such examinations—*i. e.*, Abbe's condenser and the homogeneous immersion of Zeiss—I have never succeeded in finding any cocci in these tissues, except in cases of trachoma accompanied by an active catarrhal process. But cocci are found in the secretion of granular conjunctivitis, and the disease is unquestionably contagious, and the secretion is the carrier of this contagion; but there is this peculiarity about the disease, that it requires that certain constitutional conditions shall obtain in order that the disease may be reproduced in another to whose eye the secretion has been transferred. It is a clinical fact that struma and trachoma generally go hand in hand, and *overcrowding, filth, and poor food* are the essential factors in the production of this terrible disease.

Diphtheritic Conjunctivitis.—Fortunately for us, diphtheritic conjunctivitis is a rare disease in this country. Its mode of origin and course harmonize thoroughly with the doctrine of its dependence upon pathogenic micro-organisms. Its contagiousness is undisputed, and the germ theory affords the best explanation of its phenomena; and yet, in spite of many elaborate researches, the precise nature of the diphtheritic virus is still a matter of doubt. The majority of those who have studied the question from the pathological and experimental side declare in favor of a specific micrococcus which is found imbedded not only in the membranous deposit, but also in the lymphatic spaces, beneath the mucous membrane, in the blood, and in the in-

‡ "Archives of Medicine," vol. xi, June, 1884, p. 221.

ternal organs—Oertel, Eberth, and Klebs. Loeffler * details an extensive experimental inquiry upon diphtheria in animals and man. He confirms the fact that micrococci prevail in diphtheritic membrane mingled with other forms of bacterial life, which find a suitable nidus in the necrosed and decomposing tissue; but he lays special stress, from the ætiological point of view, upon the presence of a bacillus first made known by Klebs. This organism invariably occurs in association with the micrococci, but presents, far more than these do, the attributes of a specific virus.

The micro-organism which Emmerich † alleges to be distinctive occurs in the diphtheritic lesions both of the pigeon and of man, is neither a coccus nor a bacillus, but a short, thick bacterium, which, in gelatin cultivations, forms a pellucid, grayish color, assuming a whitish appearance as it develops, and not liquefying the gelatin. It grows luxuriantly on the potato, forming on it a thick yellowish-white layer, but in blood-serum the bacterium does not grow well. In form, size, and mode of growth the diphtherial bacterium of man is identical with that of the pigeon. Inoculations were successfully made with this organism. But very great difference of opinion prevails among bacteriologists themselves as to the morphology of the diphtherial fungus. Emmerich thinks diphtheria is essentially a *house-disease*, prevailing in those seasons in which dwellings are most likely to be overcrowded.

(*To be concluded.*)

GONORRHŒA IN THE FEMALE.

By ANDREW F. CURRIER, M. D.,
NEW YORK.

(*Concluded from page 426.*)

II.—Certain forms of this disease are much better known and much more readily recognized than others. With many physicians gonorrhœa in the female is synonymous with elytritis, and it will be readily conceded that this is by far the most common form, though not always the one which is most susceptible of successful treatment. I may here repeat the statement which I made in my first paper, that the loose tissue in the posterior vaginal fornix is very commonly a source of trouble when all other portions of the mucous membrane have been cured. This area can only be exposed by the use of Sims's speculum, or some similar instrument, with a good light either direct or reflected. The mucous membrane of the cervical canal may be involved as a primary or a secondary condition, and its rich glandular structure furnishes abundant opportunity for the accumulation of infectious material, to be propagated thence beyond the os internum. In many cases, however, it is limited by the os internum, and is wholly or in part eradicated by the use of suitable means. Less frequently the urethra and bladder are affected, this being especially true of the bladder. The anatomical relations of the meatus and urethra explain the infrequency of the disease, as a primary condition, in these parts in women. The discharges of the urethra in such cases abound with gonococci, and Welander, Belleli, and others have made observations upon this subject, Belleli having obtained specimens from a large number of prostitutes at the *bureau de visite* in Alexandria, Egypt (see "Unione med. egiziana," Nov. 1, 1884). An extension from the bladder to the ureters and kidneys is a possibility, and has been referred to by Sänger, but he mentions no cases which he has seen or heard of. The condition must be one of great rarity. The vulvar glands with their ducts and circum-glandular tissue, the rectum, and the skin around the external genitals, may all, or any of them, be the seat of the phenomena of this disease; likewise the mucous membrane of the body of the uterus and of the Fallopian tubes. That an extension of the process, by way of the Fallopian tubes, to the ovaries, the parametrium, and the general peritonæum may occur, and cause fatal peritonitis, is not only a possibility, but a fact which has been observed from a period at least as remote as 1846, when Mercier published the results of his investigations in the dead-house ("Gaz. des hôp.," 1846, p. 432). In fact, Sänger states (*loc. cit.*) that this disease is the cause of a larger percentage of grave chronic abdominal diseases than puerperal fever or syphilis. The weighty evidence of Lawson Tait as to its gravity is also given as a result of *his* extensive experience (see "N. Y. Med. Jour.," 1884, p 421). Thus the profession is approaching the views that Noeggerath enunciated in 1872, which, as he prophesied, have borne fruit with the years.

A form of the disease which, until recently, was overlooked, is that which involves the peri-urethral or pre-urethral glands, and upon which papers have been written by Martineau ("Bull. et mém. de la soc. de thérap.," Paris, 1884, 2 s., xiv, 81), by his pupil Guedeney (Inaug. Thesis, "Contrib. à l'étude de la blennorrhagie chez la femme," Paris, 1883), by A. Guérin, under the name of external blennorrhagic urethritis, by Hamonic ("Ann. de dermat. et de syphil.," August 25, 1883), and by Skene in the course of a lecture upon "Vaginitis and Vulvitis" ("Med. News," Philadelphia, 1884, xliv, p. 29). The glands or follicles, which are most often the seat of this trouble, were described in 1864 by A. Guérin, and correspond to the ancient descriptions of a body which is supposed to be the analogue of the prostate. They surround, or partly surround, the urethra near the meatus, sometimes being joined in the median line, at others being separated by a bridge of tissue. Their ducts pass upward within the vestibule and open on either side of, and just under, the clitoris. The inflammation which affects them may be acute, or it may be exceedingly chronic, persisting long after all apparent symptoms have disappeared. Martineau says (*loc. cit.*) he has repeatedly found gonococci in the discharges which he has obtained from these chronic cases. If, therefore, infectious power resides in the gonococcus, we can readily see how a woman who thinks herself cured may be suffering from latent gonorrhœa, and prove unintentionally and unknowingly a source of infection. This also explains the statement of Ricord, that a woman may communicate gonorrhœa

* Friederich Loeffler, "Mittheilungen aus dem kaiserlichen Gesundheitsamte," Bd. ii, 1884, p. 421.

† R. Emmerich, "Deut. med. Wochenschrift," 1884, No. 38, p. 614.

when she does not possess it herself, which was doubtless as much of an enigma to him as his statement was illogical and absurd. Allusion has already been made to a variety of this disease to which I wish to call especial attention, because it is one of the gravest varieties, and has received considerable attention within the past year or two, notably at the hands of Lawson Tait. It is that variety which affects the Fallopian tubes. The pathology of these organs has been sufficiently investigated to inform us that, in addition to simple catarrh, hydrosalpinx, and hæmatosalpinx, there are other more serious conditions which, according to Sänger (*loc. cit.*), are usually of an infectious nature, and are either tubercular, syphilitic, actinomycotic, or gonorrhœal in character. Of these the gonorrhœal form is the most frequent. It is usually met with as pyosalpinx, but the latter is not necessarily of gonorrhœal origin. The diagnosis rests upon the discovery of gonococci. If these are found in the discharges from the genital passages, and tubal disease is evident, removal of these organs will probably reveal the organisms in the secretions which they contain, or in the mucous membrane itself. The diagnosis of tubal disease by palpation is, however, a matter of extreme difficulty, in which very few men have ever attained expertness. Even Lawson Tait says he is mistaken once in every five cases ("N. Y. Med. Jour.," 1884, p. 421). In the light of such testimony too much caution can not be observed in pronouncing opinions respecting such conditions. Autopsies upon the bodies of prostitutes have frequently revealed an inflamed, dilated, and dislocated condition of the tubes, which is at least suggestive of gonorrhœal disease, an opinion which is shared by Sänger and Tait. Finally, Sänger has described a form of this disease which he calls puerperogonorrhœal salpingitis, which may be excited in a recently delivered woman by a latent or acute gonorrhœa of her husband. Such a distinction seems quite superfluous, as it does not appear that the phenomena differ from those which are manifested in other women. The influence which gonorrhœa exerts upon fecundity was elaborately expressed by Noeggerath in the paper to which allusion has been so frequently made. In a great many cases sterility is unquestionably the result. In prostitutes especially it is fair to presume that the infrequent pregnancies are influenced by this cause. Should gonorrhœa supervene after pregnancy has been established, I have never seen that it exerted an influence upon the mother severe enough to produce a miscarriage, nor upon the fœtus any that was analogous to that of syphilis. In cases of congenital *ophthalmia neonatorum* the theory has been advanced that the gonococci traversed the fœtal envelopes and the amniotic fluid and penetrated the fœtal conjunctiva. But why such a process of selection should be followed, the eyes being chosen instead of the urethra, or some other opening which is lined with mucous membrane, does not appear. It is also probable that the eyelids are always closed *in utero*, though this might not prove an efficient barrier to the penetration of the microbes.

III.—In discussing the question of treatment, attention must be given to the value of a wise and judicious prophylaxis. Especially should prostitutes—that large class of individuals which society tolerates at such an enormous cost to itself in every way—receive attention of this character. Leaving the moral aspect of the question out of consideration for the present, although this ought to be sufficient to arouse the sympathy of any one who has the welfare of his fellow-beings at heart, it is perfectly clear that any class of individuals which distributes infectious disease in the community should be under police regulations. It matters not what the disease is, so long as it is a source of danger to the community. The reply to this may be that there is a distinction between infectious diseases which one avoids and those which one dares or defies, of which small-pox will serve as the type of one and gonorrhœa of the other. My rejoinder is that the community—the Government, State and municipal—either tolerates prostitution by taking no steps to suppress it, or it licenses it; and therefore it ought to protect the citizen from the infectious diseases which it entails. I confess that I have no elaborate scheme to offer for the accomplishment of this great end, but the remedy lies in the direction of a properly systematized medical police, with suitable hospitals or stations properly equipped; and this will come when public opinion is aroused to the necessities of the situation through the enlightened instruction of the medical profession.

Injections of sublimate, carbolic acid, iodized alcohol, dilute nitric acid, nitrate of silver, and other germicides have been recommended as prophylactic means, both for prostitutes and those who consort with them; but any one who has had experience with these classes will readily realize that this plan simply places dangerous remedies in the hands of individuals who are usually either reckless or ignorant in their use of them. Another important point in connection with the subject of prophylaxis has reference to the consummation of marriage on the part of women who are suffering, or have suffered, from gonorrhœa, and such women are by no means confined to the class of prostitutes, as any physician of experience is able to testify. Any one who has seen the mischief which is wrought in families by the discovery of such a condition will surely make the requirements not less stringent before giving his professional consent to marriage than if the gonorrhœa had been in the male instead of the female. As long as gonococci can be found in the discharges, that consent should be unhesitatingly withheld. The pathogenic nature of the micrococcus being admitted, the treatment will naturally be directed chiefly at its vitality. Whatever theory be adopted as to the nature of the disease, those agents must be used which will stop the offensive discharges, relieve congestion, and produce a healthy tone of the affected tissues with their vessels and nerves. Oppenheimer has made a large series of experiments bearing upon this subject, which are both interesting and important (*loc. cit.*). He first tried to cultivate gonococci by using fresh gonorrhœal pus from a patient in the acute stage of the disease who had not yet been treated. The pus was mixed with one part urine gelatin, two parts water, and three per cent. of meat-peptone. This experiment was unsuccessful, but was followed by one which was successful, in which sterilized blood-serum was used as the cultivation-fluid. The microbes were developed

upon pieces of thread which were laid in the serum.* No effect was produced upon their vitality by solutions of subnitrate of bismuth, acetate of lead, or alum. Slight effect was produced by strong solutions of sulphate of copper, zinc, or iron, and chloride of zinc. Development was arrested by a two-per-cent. solution of nitrate of silver.†

Of the mercurials, a solution of 1 to 15,000 of the nitrate or sulphate retarded development, 1 to 10,000 destroyed vitality; 1 to 40,000 of sublimate retarded development, 1 to 20,000 destroyed vitality. Solutions of mercurial salts in glycerin were equally effective with watery solutions. Chlorate of potassium or of sodium in solution was ineffective, the former being used to the limit of saturation. Permanganate of potassium was destructive in 1-to-25 solutions; in 1-to-50 solutions it retarded development; it was entirely inert in the weak solutions which have been recommended by Zeissl. Moderately strong solutions of bromine, chlorine, and iodine destroyed the microbes, while methylic and ethylic alcohol, sulphuric ether, glycerin, and chloroform were effective only when used undiluted. Tannin and resorcin were inert. Five-per-cent. solutions of carbolic acid destroyed life in ten minutes; one-per-cent. solutions only retarded development. Watery solutions of thymol and salicylic acid of sufficient strength to excite inflammation in normal tissues did not kill the organisms, while alcoholic solutions of the same strength were efficient. This is the more remarkable since alcohol alone was not destructive. Fifty-per-cent. solutions of creasote were rapidly fatal. Turpentine was quite effective; balsam of copaiba and cubeb extract were harmless. It was thought possible that the well-known efficiency of cubebs and copaiba in the practical treatment of gonorrhœa might be due to chemical changes which the drugs underwent in the system. This matter was tested by using specimens of urine drawn from the bladder of a pregnant woman through a heated metallic catheter. The urine was normal in character and had no influence upon gonococci. Two doses of copaiba balsam were then given to the patient, of fifteen grains each, and with an interval of three hours between them. The urine was then drawn with the precautions mentioned, and was found to contain conversion products (Umsetzungsproducte) of the balsam. Threads upon which cocci had been developed were immersed in this, and allowed to remain eighteen hours. At the end of that time they were transferred to a cultivation-fluid, but no development occurred. The same result followed experiments with cubebs. The supposition is therefore warrantable that these substances undergo chemical change, and, after elimination by the kidneys, perform their work upon the cocci in the genital tract. Oppenheimer's conclusion is that only sublimate, creasote, and nitrate of silver are of any practical use for the destruction of gonococci, and he is entitled to a respectful hearing, for no one, apparently, has investigated this subject more exhaustively or patiently. There is a factor, however, which is not embraced in any investigation of this character—namely, that of idiosyncrasy or personal peculiarity, and the mysterious changes which occur within the tissues and cavities of the body can not be exactly reproduced outside the body, because the conditions can never be exactly the same. It is, therefore, clinical rather than purely experimental results by which we must finally be guided. To illustrate, Oppenheimer found solutions of chlorate of potassium inert in their effect upon gonococci, but a gentleman of extensive experience assured me that they were quite efficient, with him, in subduing all the phenomena of gonorrhœa. Oppenheimer found resorcin inert, but Martineau (*loc. cit.*) obtained good results from its use. Rebatel recommends a weak injection (vaginal) of salicylic and citric acids, or of a decoction of lemon, for their efficiency in the gonorrhœa of females, which would, doubtless, have little effect upon Oppenheimer's cultivated gonococci. On the other hand, I have found, in a large number of cases, that the sublimate treatment (that is, by local applications) was quite unsatisfactory, and this experience is similar to that of Kroner, Schatz, and von Tischendorf. Oppenheimer places it at the head of the list of gonococcicides. Von Tischendorf's best results were with irrigations of acetate of aluminium and applications of iodoform. I have tried the latter many times without positive results. The best results which I have seen have been mainly from free applications of a mixture of glycerin and subnitrate of bismuth. Allow me to narrate a typical case in which the results of this treatment were quite a revelation to me:

A young unmarried woman came under my observation with gonorrhœa in an intensely acute form. The urethra was evidently involved, the mucous and submucous tissues of the vagina were inflamed and infiltrated, and there was also inflammation of the mucosa of the cervix. There was no question as to the diagnosis, as the man with whom she had cohabited was also suffering with gonorrhœa. Applications of sublimate, eucalyptus, iodine tincture, etc., were tried for two or three weeks without success. The patient was then informed that she must give up her occupation (that of book-keeper), remain in bed for a season, and receive such treatment as seemed necessary. A mixture of subnitrate of bismuth and glycerin was at hand, and a tampon saturated with this was used empirically. Two days later the tampon was removed, and, to my surprise, the congestion and sensitiveness of the inflamed portions were greatly modified, and the offensive discharge had greatly diminished. This treatment was, therefore, continued, with applications of iodoform, every day, and after a week every other day, the tampon remaining ten or twelve hours. Vaginal douches of hot water were also very carefully given once or twice a day, after the removal of the tampon. Liquid food was taken, and an abundance of alkaline drinks. In three weeks every trace of the disease had disappeared, and the patient had resumed her occupation.

I have frequently used the subnitrate of bismuth and glycerin mixture since the experience described, and always with satisfaction. Its function consists in a free depletion of the congested tissues and a very decided astringent action. The proportion of a drachm of bismuth to an ounce of glycerin may be used, the mixture being, apparently,

* The vitality of the microbes was seen in the fact that they survived the drying of the cultivation-fluid, and this fact may be of importance in explaining some obscure cases of infection in which all necessary precautions are supposed to have been taken.

† This is the solution which was recommended by Credé a few years ago as a prophylactic against *ophthalmia neonatorum*, and has come into very general use for this purpose.

only a mechanical one. Such a mixture may not be directly destructive to gonococci, but, by the modifying action which it has upon the secretions, it deprives them of the qualities which are necessary to cultivation-fluids, and thus the microbes die of starvation. Whatever method of treatment is chosen, it must be carried out persistently and systematically, even to the last detail. It will not be enough to prescribe vaginal injections or uterine applications of this or that; the physician must be certain that they are used, and, if necessary, must attend to or superintend the details himself. Especially is this true in regard to those obscure forms of the disease which affect the glands and ducts of the urethra, vulva, vestibule, and fourchette. Abscesses and fistulæ may be results of the disease in these parts, and, in addition to the list of drugs for local application, it must be borne in mind that it may be necessary to use the knife or actual cautery before the disease can be overcome. Such a course has been recommended by Guedeney, Martineau, and Vidal de Cassis. If the given symptoms point to an extension of the disease to the tubes and ovaries, the question of abdominal section becomes a pertinent one. I believe that this operation is done too often. It is not sufficient that an operator can show a good percentage of recoveries after salpingo-ovariotomy; he must show positive results flowing from the removal of important organs in which, in many cases, no disease is traceable either by the naked eye or the microscope. Many plans of treatment are available before a woman should be submitted to the risks and uncertainties of a capital operation. Concerning the curability of the disease, Noeggerath's paper declared that he did not think this possible, and I have seen no statement from him to the contrary, though Neisser's doctrine was announced seven years after the first publication of that paper, and may have modified his views. Bumm believes that it may be entirely recovered from, and that it is amenable to treatment according as the area of infection is moderate in extent and near the surface. Arnaud has observed that it can be considered radically cured only when the menses have become regular and when metrorrhagia and other symptoms and complications have ceased ("L'Union méd. du Canada" [from "Abeille méd."], May, 1885, p. 223). This statement is unsatisfactory, however, for there are many cases in which neither metrorrhagia nor any irregularity of the menses occurs at any time. My own belief is that it depends upon the gonococcus for its activity; that if the mucous membrane, with its innumerable crypts, follicles, and glandules, is treated with sufficient thoroughness by either of the efficient germicides which have been mentioned for a sufficient length of time, which will vary with the extent of tissue involved and the potency of the secretions which serve as cultivation-fluids for the gonococci—that if these conditions are fulfilled the disease can be cured, for dead organisms can not reproduce themselves. Of course, this statement has no bearing upon the question of reinfection which, so far as I know, is at any time possible.

A few days ago I saw a lady who first came to me more than two years ago with gonorrhœa, which was very obstinate and rebellious to treatment. For more than a year she was almost constantly under observation, and at the end of that period I considered her cured. Since then there have been no clinical manifestations pointing to a recurrence of the disease, therefore I see no reason why her cure should not be considered positive, and I believe the same would hold equally true in any similar case.

38 West Thirty-sixth Street.

VALVULAR ANEURYSM.*

By ALBERT BRINKMAN, M. D.,
BROOKLYN.

The specimen I present is one of disease of the aortic and mitral valves, accompanied by valvular aneurysm of one of the leaflets of the mitral valve. The subject from whom it was taken was a man of tall and muscular physique, who entered my service at Charity Hospital, giving the following history:

John M., aged thirty-eight years, native of Ireland, and a blacksmith by occupation, enters complaining of œdema of both legs. Admits the abuse of alcohol, but denies all history of rheumatism; to use his own words, if he ever had rheumatism he was not aware of it. No evidences of syphilis obtainable. Two years ago he first noticed swelling of both ankles, and that he easily became short of breath on exertion. Applying to a dispensary, he obtained some medicine (presumably digitalis), which caused the œdema to disappear. Within the last few months the swelling has increased to such a degree as to extend up both legs to the knee joints.

Physical examination reveals an increased area of the apex beat, which, on palpation, is found displaced to the left, and downward on a line with the left nipple; the beat is not distinct, but rather diffused. A murmur is heard, commencing before and taking the place of the first sound of the heart. It is a continuous murmur, which begins before the ventricular systole and continues until the second sound of the heart; it has its maximum intensity at the apex. This murmur, or (presuming it to be a double one, mitral, obstructive, and regurgitant) part of it, is conveyed to the left and heard behind.

At the base there is a murmur with both sounds of the heart, or, as it is generally termed, a see-saw murmur. The systolic portion is heard in the vessels of the neck.

Diagnosis.—Aortic obstruction and regurgitation; mitral obstruction and regurgitation.

Urine examined. Albumin found, but no casts.

Treatment.—Inf. digitalis, ℥ ss., t. i. d., which caused great diminution in the œdema, but also the development of digitalis poisoning after one week's administration. The digitalis was stopped for a few days, and ext. convallariæ maialis fl., gtt. xv, t. i. d., substituted. In three weeks, the œdema growing worse, he was again put on digitalis.

The patient died after being in hospital one month.

The autopsy showed a greatly hypertrophied heart, the weight of which, after its cavities were freed from blood, was twenty-four ounces. This is a maximum weight for a heart with combined aortic and mitral disease, a heart with both of these lesions generally being intermediate in weight between that which obtains in the two separate forms of the disease, the organ being lighter than in aortic and heavier than in mitral disease. Sibson gives cases of this kind in the male as averaging from 14 ℥ 8 ℨ to 21 ℥ 8 ℨ. The extremes of mitral disease are 14 ℥ to 18 ℥; the extremes of aortic disease are 14 ℥ to 46½ ℥, the latter being that of a case of aortic obstruction mentioned by Bristow.

* Read before the Brooklyn Pathological Society, May 14, 1858.

Upon opening the heart, contraction and thickening of the aortic valves were found, with calcareous incrustations and vegetations. The mitral valve, besides being insufficient, shows a valvular aneurysm of its posterior leaflet.

Sibson, in "Reynolds's System of Medicine," gives the mode of development of these pouches, or aneurysms, as follows. After speaking of the ordinary pathological lesions found in mitral disease, he says: "Sometimes, however, the inflammation deepens at its original seat on the surfaces of contact of the mitral valves and extends beyond those surfaces, so as to affect a large portion of the flaps of the valves on their ventricular surface. Under these circumstances the inflamed, softened, and thickened structure may undergo granular degeneration, and its ventricular layer become broken or ulcerated. The auricular layer of the valve thus tends to yield before the pressure of the blood, which forces its way through the breach into the ventricular layer, and to form pouches or aneurysms protruding into the left auricle." I may mention that the process may stop here, or, as Sibson goes on to say, "the auricular layer may then be involved in the inflammation, and become in turn subjected to granular disintegration and breaking up of tissue, so that the flap of the valve may become perforated." This has been the case in the specimen before you, after the formation of the pouch perforation has occurred into the auricle.

Now, we know that the mitral valve is peculiarly liable to these aneurysms—more so than the aortic valves. It is comparatively seldom that we meet with them on the aortic valves. This predisposition is readily accounted for if we glance for a moment at the action of the mitral valve. "The mitral valve is closed on exactly the same principle as the aortic valve—namely, by the pressure of the blood, driven during the ventricular systole into the small open cells on the under or ventricular surface of the valve. The force with which the blood presses upon the closed mitral valve, the closure of which is caused by the contraction of the ventricle, is much greater than the force with which the blood presses upon the aortic valve, the closure of which is caused by the recoil of the previously distended walls of the aorta. The flaps of that valve—namely, the aortic—are pressed together by the backward portion only of the effect of the recoil of the aortic walls, which expends itself in every direction; and that force of recoil is itself but a portion of the original propulsive force of the left ventricle, which presses with its full power upon the closed mitral valve. The surfaces or lines of contact or closure of the mitral valve extend along and just within the borders of its two flaps. This border of contact is not a mere edge, but a surface or line of adaptation, made up of the small bead-shaped cells that dovetail into each other along the margins of the flaps; the result is that the margins of contact of the mitral flaps press against each other, when the valve is closed, with much greater force, tension, and concentration than the margins of contact of the aortic valve."

Taking this view of the action of the mitral valve, it is seen that this valve is subject to valvular aneurysm because of the great amount of pressure brought to bear against it in the ventricular systole, and also because endocarditis does not attack the very edges of the mitral valve, but the margin just within its edges; and after an endocarditis has occurred, with its production of new tissue, and this new tissue undergoes fatty, granular, or calcareous changes, ulceration sets in on the body of the valve; this ulceration either goes on to perforation, causing rupture of the valve and consequent regurgitation, or the structure of the valve becomes so attenuated that a portion of it yields to the blood-pressure and forms a pouch or valvular aneurysm. Again, the mitral valve, which is situated in the muscular center of the ventricle, and in the focus of its internal inflammation, must be more prone to these aneurysms than the aortic valve, which has broader surfaces of contact, less pressure of blood, and no tendinous traction. To demonstrate further that the pressure is greater against the mitral than against the aortic valve, take a case of aortic valvular aneurysm; instead of the pouch protruding in the direction of the aorta, the aneurysm protrudes downward into the ventricle. Therefore, to cause these pouches to protrude into the ventricle, the blood-pressure must be greater on the aortic side of the valves than on the ventricular; but the pressure produced by the aortic recoil is decidedly less than that caused by contraction of the ventricle, as I have before proved.

HYDRONAPHTHOL;
A NEW ANTISEPTIC.

By GEORGE R. FOWLER, M. D.,
SURGEON TO ST. MARY'S GENERAL HOSPITAL, BROOKLYN.

(*Continued from page 404.*)

At my request, Mr. Max Schwarz, of New York, Superintendent of the Technical School for Brewers, known as "The First Station of the Art of Brewing," etc., and late a pupil of Prof. F. Cohn, of Breslau, Germany, made the following experiments upon the antiseptic powers of hydronaphthol at his laboratory:

In the first instance the following incubation liquid was prepared, viz.:

Distilled water.....	1 litre;
Chemically pure grape-sugar.....	100 grammes;
Potassium phosphate.....	30 "
Ammonium nitrate.....	30 "

This was sterilized by boiling for thirty minutes.

This liquid was divided in ten equal parts as follows:

Part	I,	containing no hydronaphthol.						
"	II,	"	1	part in	9,000	parts	of	the liquid.
"	III,	"	1	"	8,000	"	"	"
"	IV,	"	1	"	7,000	"	"	"
"	V,	"	1	"	6,000	"	"	"
"	VI,	"	1	"	5,000	"	"	"
"	VII,	"	1	"	4,000	"	"	"
"	VIII,	"	1	"	3,000	"	"	"
"	IX,	"	1	"	2,000	"	"	"
"	X,	"	1	"	1,000	"	"	"

Of each of these above-named liquids four equal parts were incubated in the following sequence, after all had been sterilized by boiling beforehand, with the germs of the following fungi:

Penicillium glaucum,
Mucor mucedo,
Aspergillus niger,
Sterigmatocystis nidulans.

After incubation these culture-liquids, forty in number, were placed in an air water-bath (incubator) which was kept at a temperature of 24° C. for forty-eight hours. After the lapse of this time a strong fungoid growth could be perceived in all the control tests, which latter, of course, did not contain any hydronaphthol, while all the liquids containing hydronaphthol had remained clear and free from fungoid growth, and remained so for more than five days, when they were disposed of.

These experiments prove that hydronaphthol, in proportion of 1 to 9,000, prevents the development of these germs. Even more diluted solutions of hydronaphthol may possess antiseptic action, but exact observations have yet to be made in order to ascertain the limit of its antiseptic power. This, of course, would be of highly scientific interest, but for practical purposes the above given proportion of 1 to 9,000 may be sufficient in all cases where inhibition of the germs of this class is desired.

A second series of investigations into the antiseptic properties of hydronaphthol was conducted as follows.

To each of the above-named solutions the compound was added as follows:

1 part of hydronaphthol in 9,000 parts of the solution.
1 " " " " 8,000 " " "
1 " " " " 7,000 " " "
1 " " " " 6,000 " " "
1 " " " " 5,000 " " "
1 " " " " 4,000 " " "
1 " " " " 3,000 " " "
1 " " " " 2,000 " " "
1 " " " " 1,000 " " "

and a control-test, free from hydronaphthol.

After careful sterilization by means of boiling, to these were added three cubic centimetres of a suspension of the best, purest, and healthiest beer-yeast (*saccharomycis cerevisiæ*); these were well agitated, and then kept quiet for four days, all being well protected from the germs floating in the atmospheric air by closing the mouths of flasks containing these liquids with sterilized cotton-wool.

After four days' standing, about one tenth of each of these liquids was distilled off separately, and the ten different distillates tested for alcohol by addition of a solution of iodine in a potassium-iodide solution rendered alkaline by means of potassium hydrate.

After twenty-four hours' standing the precipitates thus formed were examined under the microscope, and the following results obtained:

In the distillate of the solution containing no hydronaphthol, iodoform was found.
In the distillate of the solution containing
1 part hydronaphthol to 9,000, iodoform was found.
1 " " " 8,000, " " "
1 " " " 7,000, " " "
1 " " " 6,000, " " "
1 " " " 5,000, " " "
1 part hydronaphthol to 4,000, iodoform was found.
1 " " " 3,000, " " "
1 " " " 2,000, no iodoform was found.
1 " " " 1,000, " " " "

From these experiments the conclusion is to be drawn that 1 part of hydronaphthol dissolved in 2,000 parts of a solution which, under ordinary circumstances, ferments readily with yeast, is capable of holding in check this fermentation. Microscopic examination showed that in the liquids containing hydronaphthol in the proportions of 1 to 1,000 and 1 to 2,000, the yeast-cells presented the appearances of a coagulated protoplasm, while those in the other liquids showed a good and healthy protoplasm.

The foregoing experiments confirm the observations made at the Johns Hopkins University laboratory concerning the inhibitory antiseptic effect of this compound. The hope that a positive germicide effect may yet be demonstrated is suggested by the results of these observations and the extremely dilute solutions found to be efficient in the inhibiting of these organisms.

The following series of cases is herewith presented, comprising my experience up to the present date, in the practical application of hydronaphthol to surgical practice. Some interesting points are worthy of mention, among others the fact that the application of the powder directly to the skin was not without some disadvantages, in that it produced irritation, and in two cases, at least, was responsible for a failure to secure union by first intention. These cases, however, continued to pursue an aseptic course. When the hydronaphthol was diluted in a two-per-cent. trituration with carbonate of magnesia, this feature was no longer noticeable, and the value of the new antiseptic was ully demonstrated.

Case I.—*Floating Body in Knee-Joint.*—Mrs. G., aged fifty-six, for several years past has suffered from sudden pain in knee joint, especially while ascending or descending a stairway. This was followed frequently by an attack of synovitis. Recently these attacks have recurred with increasing frequency, and she became clamorous for relief. Examination revealed the presence of a floating body in the joint. On September 14, 1885, I opened the joint, having failed in an attempt to fix the body for the purpose of cutting down directly upon it. I passed my finger into the interior and searched for and removed the body. It proved to be of the shape and character usually found under these circumstances, and of about the size of a hazel-nut. The joint was thoroughly irrigated with a warm solution of hydronaphthol, 1 to 1,000, a few strands of catgut introduced for purposes of drainage, the wound closed with a continuous catgut suture, pure hydronaphthol dusted over the wound, a sawdust cushion which had been saturated in a hot alcoholic solution of hydronaphthol and then dried was then bandaged over the wound, a well-padded back-splint applied, and the patient placed in bed. No pain, fever, nor other untoward circumstance occurred to give me any uneasiness in this, my first case of importance in which the new antiseptic was used. At the end of fourteen days I removed the dressings for the first time, flexed the limb at a right angle, and in a few days the patient was walking about—well. There was an excoriated spot near the line of union, which a subsequent experience led me to believe that the hydronaphthol, applied as it was in its undiluted state, was responsible for.

Case II.—*Excision of Entire Radius.*—E. I., aged nine and a

half. Osteo-myelitis of the left radius. Operation September 14th, at St. Mary's General Hospital. Incision entire length of radius, upon outer and posterior aspect of arm. Bone sawed through middle with chain-saw, and each half separated from periosteum and removed. Hydronaphthol solution, 1 to 1,000, used for irrigating; drainage-tube of soft rubber placed in position; sutures of catgut; pure hydronaphthol dusted along line of sutures and wood-flour dressing applied. Dressings first changed, on account of profuse discharge, on eighth day. Edges of wound united at intervals, primary union taking place, perhaps, in the aggregate, in about one half of the length of the incision. The skin about the points where union had not taken place was red, and in spots presented an excoriated appearance; this latter being due, no doubt, to the pure hydronaphthol dusted upon the edges of the cut surfaces. The wound was irrigated as before and redressed, and healing thereafter proceeded without interruption. No rise of temperature after third day.

Case III.—*Wry Neck; Open Section of Sterno-cleido Mastoid.*—M. S., aged eight. Wry neck resulting from measles four months ago. Sterno-cleido mastoid contractured. September 18th made section of the muscle, both at its clavicular and sternal attachments; irrigated with hydronaphthol solution; catgut drain and sutures. Dusted hydronaphthol and carbonate of magnesia (two parts to one hundred) along line of incision; dressed with wood-flour sterilized with corrosive sublimate, and rendered antiseptic by hydronaphthol. Head retained in position by plaster-of-Paris dressing, including chest, shoulders, and head. No fever, pain, nor other disturbance. Entire dressing removed on twentieth day. Wound healed perfectly; no pus.

Case IV.—*Wood's Operation for Radical Cure of Hernia.*—E. M., aged fourteen. Inguinal hernia, left side, of several years' standing. Has tried many trusses, but, owing to sensitive skin and extremely nervous condition of child, were abandoned. The parents solicited an operation for his relief. September 23d, operation of Mr. John Wood performed. Silver-wire suture. Hydronaphthol solution, 1 to 1,000, used for irrigating. Wound in scrotum left open; dressings of wood-flour and hydronaphthol applied. No fever nor other cause for anxiety. Wire and last dressings removed on fifteenth day. Needle punctures closed in twenty-four hours; wound in scrotum granulating in a healthy manner Ointment of hydronaphthol (ʒ ss. to ʒ j) ordered for latter. Discharged, cured, on twentieth day.

Case V.—*Ligature of Femoral Artery for Elephantiasis.*—Mrs. C., aged forty-eight, admitted to hospital September 23d. Elephantiasis arabum of both lower extremities below knee joint of four years' duration. Patient an opium *habitué*. Operation of ligature of femoral above profunda on September 24th. Irrigation by means of hydronaphthol solution, 1 to 1,000. Pure hydronaphthol sprinkled along line of sutures. Wood-flour-cushion dressings and a spica bandage applied. No fever, but dressings had to be removed on fourth day on account of profuse serous discharge. Skin along line of sutures irritated and in some places excoriated. Union for about one third of the length of wound only; deeper portions of wound united. Dressed thereafter with an ointment of hydronaphthol (ʒ ss. to ʒ j). Granulating healthily.

The limb was at first cold and of a yellowish gray color; in a few hours it became warm. In eight days it was found to have been reduced in size fully one third. Case still under observation.

Case VI.—*Strangulated Hernia; Operation.*—E. W., aged seventeen. Right inguinal hernia had existed for several years; for last two or three years had worn no truss. Hernia had not been reduced completely for four months. Admitted to St. Mary's General Hospital, September 24th. When seen by me was in acute general peritonitis, fæcal vomiting, knees drawn up, countenance drawn and anxious, pulse small and thready, surface cold and clammy. Symptoms of strangulation had existed for six days prior to admission. Stimulated freely; three hours later herniotomy performed; sac opened; gut believed to be yet in good condition, so far as could be ascertained. Large mass of omentum excised, and some portions adherent to canal were brought up and stitched with catgut to internal ring with neck of the sac. Hydronaphthol, 1 to 1,000, used for irrigating, and pure powdered hydronaphthol dusted along line of incision; wood-flour dressings applied. Patient rallied after vigorous stimulation. Dressings removed on fourth day, owing to their becoming disarranged by restlessness of patient. Deeper portions of wound found to be healed. Integumentary margins were found to have been irritated, swollen, and gaping. Sutures of catgut had softened by the copious exudation from the wound edges, and had given way. Granulation went rapidly on; peritonitis rapidly subsided; bowels moved spontaneously on the seventh day. Patient sat up on the twenty-first day. The wound rapidly granulated under the application of hydronaphthol ointment (ʒ ss. to ʒ j).

Case VII.—*Perforating Wound of the Elbow Joint.*—J. C., aged eight. Upon the evening prior to applying at my office, September 24th, while reaching up to unlatch an area-gate, his foot slipped from the stone step, and his left arm was caught upon one of the iron pickets of the gate. He called for assistance, and his mother lifted him from the sharp iron rod upon which he hung. A ragged wound was found upon the inner border of his arm, near the posterior surface. A dressing of vaseline was applied. The boy complained greatly of pain, and the following morning he was brought to my office. The joint was very much swollen, hot, and tender. Synovial fluid was escaping from the wound. A probe, passed along the wound track, entered the joint midway between the inner condyle of the humerus and the olecranon process of the ulna. Pulse 130, temperature 102½°. Wound surroundings and joint irrigated for several minutes with warm solution of hydronaphthol, 1 to 1,000, drainage-tube introduced, parts dusted with hydronaphthol and magnesia (2 to 100). Paper-wool and hydronaphthol dressing and trough-splint applied. In twenty-four hours temperature reduced to 99°; pulse to 80. Pain had entirely disappeared. Dressings removed on the fourth day for the purpose of removing the drainage-tube; for this latter catgut drains were substituted. Arm was found to be normal in size and appearance. On the fourteenth day following the injury the dressings were again removed, when the wound was found to be healed, with complete movement in the joint.

Case VIII.—*Osteo-sarcoma of Tibia.*—Mrs. M., aged fifty-four. Blow upon middle third of left tibia about four months prior to operation. Admitted to St. Mary's General Hospital, October 2d. Large mass of broken-down sarcomatous growth (fungous hæmatodes) upon anterior aspect of tibia, at about its middle. Amputation at knee joint performed October 5th by lateral-flap method. Hydronaphthol irrigation (1 to 1,000); rubber drainage-tube; hydronaphthol and carbonate of magnesia (2 per cent.) were well triturated together and dusted along line of sutures. Dressings of wood-flour cushions applied. No rise of temperature, pain, nor other inconvenience. Dressings not disturbed until tenth day. Parts aseptic; drainage-tube removed; union perfect; no irritation. Cushion of wood-flour reapplied to small opening through which drainage-tube had emerged.

Case IX.—*Compound Fracture of Leg.*—T. W., aged eight, school-boy. Brought in by ambulance October 8th. Heavy truck-wheel had passed over his left tibia and fibula at the junc-

tion of the upper with the middle third. Wound leading down to fibula admitting my index-finger; another over tibia, about an inch and a half long. Surrounding parts and wound itself thoroughly washed and deeper portions irrigated with hydronaphthol solution, 1 to 1,000. Several strands of catgut were passed from bottom of each wound through the soft parts; hydronaphtholated magnesia and wood-flour cushion dressings applied; limb supported in a wire-cloth splint and suspended. No pain since dressings were applied; slight fever at end of first twenty-four hours, which subsided in a few hours without any treatment. Primary dressings still *in situ* at present writing (October 19th, eleventh day), and these will not be disturbed, unless some special indications exist, until bony union is believed to have taken place.

Case X.—*Supra-condyloid Osteotomy for Genu-varum.*—Rosie K., aged thirteen. Three months previously I performed excision of the knee joint for tubercular osteitis of the inner femoral condyle and head of tibia. Owing to extremely thin shell of bone left after gouging out with Volkmann's sharp spoon cancellous tissue of condyle and head of tibia, good apposition of the parts was not obtained, and, when the dressings were finally removed, the limb was found to be in the position of genu-varum. To correct this, a supra-condyloid osteotomy, after the manner of Macewen, was done on October 8th at the hospital. The incision, however, was made upon the outer instead of the inner border of the thigh. Catgut drain inserted; wound sutured; hydronaphthol in carbonate of magnesia (2 per cent.) dusted along line of sutures; wood-flour cushion dressing and plaster-of-Paris splint applied. No fever, pain, nor discharge has occurred up to present writing (October 19th). It is not expected that the dressings will be removed in this case until union of bone is believed to be complete.

Case XI.—*Fibrous Tumor at Site of Pre-trochanteric Bursa.*—J. H., aged forty-seven, Egyptian sailor. Admitted to hospital on account of growth over right trochanter. Fell from rigging of vessel some years ago and received an injury to the bursa in this region, which led to suppuration. Since then there appeared the present growth, which has grown slowly, and of late has occasioned him some inconvenience, and at times been tender and painful. Operation of excision October 8th; hydronaphthol solution, 1 to 1,000 for irrigation, etc.; catgut drains. Hydronaphtholated magnesia (2 per cent.) and wood-flour cushion dressings held in position by spica. Dressings found disarranged, and therefore changed on fourth day. Union progressing along entire line of incision; no irritation or discharge; case thus far afebrile and painless (eleventh day).

(*To be continued.*)

COCAINE ANÆSTHESIA IN FEMORAL SUPRA-CONDYLOID OSTEOTOMY AND EXCISION OF THE HIP JOINT.*

By MILTON JOSIAH ROBERTS, M. D.,

PROFESSOR OF ORTHOPÆDIC SURGERY AND MECHANICAL THERAPEUTICS IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL; VISITING ORTHOPÆDIC SURGEON TO THE CITY HOSPITALS ON RANDALL'S ISLAND, ETC.

The temporary character of the local anæsthetic effect of cocaine, thanks to the brilliant suggestion of Dr. Corning,† is a thing of the past. It is now possible to prolong this effect of the drug to any desired extent by simply obstructing the circulation of the blood through the tissues into which it is injected, thus effectually preventing its escape from the area desired to be rendered anæsthetic.

In the "Medical Record" of this date, October 17th, will be found a communication from me on cocaine in bone surgery, with a description of my first operation. I now desire to report two additional operations performed, under cocaine anæsthesia, this afternoon. These operations were both performed in one of the Randall's Island hospitals, and one or both of them witnessed by Dr. James R. Healey, Dr. E. L. Cocks, Dr. G. H. Cocks, Dr. C. C. Bradley, Dr. Stephen Vittum, Dr. O. C. Tarbox, Dr. M. J. Rockwell, Dr. G. D. Wheat, and Dr. R. Lewis, the six last-named gentlemen composing the house staff and assisting in the operations.

Before describing the operations in detail, however, I may remark that they were undertaken with the idea of making a crucial test of the efficacy of the method of local anæsthetization employed. Just what advantages this particular method possesses, and the determination of the range of its practicable applicability, are questions which can not be satisfactorily answered by the results obtained in a few experimental operations. It is possible, nevertheless, by the elimination of obvious sources of error, to determine the probable extent, profundity, durability, and regularity in the production of the local anæsthetic effects of the drug.

My first operation, above referred to, was for elbow-joint disease. It involved, in addition to the extensive division of soft tissues, the excavation of the entire inner condyle of the humerus and part of its outer condyle. Though a small drill-hole was made transversely through the upper end of the ulna, which bone, upon microscopical examination of the *débris* thus removed, was ascertained to be in a healthy condition, the main part of the operation was confined to the removal of diseased bone, and therefore the parts divided might not have been possessed of their normal degree of sensitiveness. This source of error, as will appear, does not require to be considered in the operations now to be reported upon. Again, my first patient, though a delicate female in an exceedingly apprehensive frame of mind, was an adult. The question arose, Was the method also applicable to operations on children? Then, too, there was the question of fear and mental excitement, which forced itself into recognition, when considering the possible causes of the manifest absence of pain during the operation.

Femoral Supra-condyloid Osteotomy for Genu Valgum.—The first operation which I have to report was performed upon a boy about four years of age. Some months ago, the patient being ætherized, I did four cuneiform osteotomies upon the bones of his legs in their lower third for the correction of anterior curvatures. There remained marked genu valgum of the left limb. When placed upon the operating-table on this occasion, the little fellow showed some signs of fear. Applying a fine needle, half an inch in length, to a hypodermic syringe containing a freshly made five-per-cent. solution of cocaine (Merck's), I made super-

* Reported to the Clinical Society of the New York Post-Graduate Medical School and Hospital, October 17, 1885.

† "On the Prolongation of the Anæsthetic Effects of the Hydrochlorate of Cocaine when Subcutaneously Injected. An Experimental Study." By J. Leonard Corning, M. D. "New York Medical Journal," September 19, 1885.

ficial injections over the inner anterior aspect of the thigh just above the knee. The successive injections, for the most part, were made into the periphery of the area of redness (ischæmia) resulting from previous injections. Whenever this rule was deviated from the child would wince and complain of pain, though he did not cry out. For the purpose of anæsthetizing the deeper tissues, the short needle was replaced by one an inch long and the injections were continued. Having secured anæsthesia along the line of Macewen's incision, an Esmarch's bandage was applied from the toes up to the knee joint, where it was fastened. A second Esmarch's bandage was continued from this point up the limb to about five inches above the joint. Here the thigh was encircled by a strong elastic band, and the Esmarch's bandage last applied removed, exposing that segment of the limb to be operated upon. The bandage first applied was left in position throughout the operation. Three or four injections down to the bone were made along the proposed line of incision. The knife was now carried down to the bone along the same line, making an incision two inches and a half long. The child made no complaint whatever. Introducing the needle of the syringe through the wound thus made I injected six or eight minims under the periosteum and into the tissues above (in front) and below (behind) the bone, in order that the passage of my retractors between the bone and soft parts, as well as the subsequent section of bone, might be rendered painless. Upon my attempting to introduce the retractor, the child evinced discomfort when I reached the outer aspect of the bone. I immediately withdrew the retractor and injected about four minims down to the bone and under the periosteum, on the outer aspect of the thigh. This enabled me to proceed with the introduction of the retractors without complaint on the part of my little patient. The retractors being introduced and the soft tissues drawn back, freely exposing the bone, I quickly removed a cuneiform segment from the femur just above the epiphysis, by means of my electro-osteotome. Again no pain was manifested by the child. The Esmarch's bandage and elastic girdle about the thigh were removed, the wound was closed and covered with antiseptic dressing, and the limb brought into line and secured in position by means of a gutta-percha splint. During this latter procedure and the first punctures of the hypodermic needle the child complained slightly of pain. At all other times during the operation he manifested no discomfort. He was laid upon a cot near by and watched the subsequent operation with apparent delight, for whenever I looked at him he smiled pleasantly, and, when questioned, answered cheerfully. In this operation three grains of cocaine were injected.

Excision of the Hip Joint.—Encouraged by the results thus obtained in the cocainization of bone and overlying soft tissues, I proceeded at once to try the efficacy of local anæsthesia in excision of the hip joint, there being a patient in the ward awaiting this operation. The subject of the second experimental operation was a girl about six years old who had suffered from hip disease for many months. An abscess, the result of the morbid process going on in the bone, had opened spontaneously and was discharging its pus through a fistulous opening.

The superficial and deep structures were cocainized in the same manner as before, a two-and-a-half inch needle being used for the deepest injections. I had not proceeded far when I was informed that my supply of cocaine was exhausted. A messenger was immediately sent for more cocaine solution, but could only procure a four-per-cent. solution which had been made up several days. With this I continued the injection until I had apparently secured profound anæsthesia along the intended line of incision. A strong elastic band was tied about the proximal end of the thigh. With his fingers placed under it on the outer aspect of the limb, an assistant stretched this band and drew it upward over the crest of the ilium. The pressure thus produced was sufficient to interfere with the superficial circulation. No means were at hand for compressing the abdominal aorta. The usual incision for exsection of the joint was made down to the bone. The patient complained considerably of pain, but did not cry out. Cocaine was injected through the wound into the tissues about the upper end of the bone. Injections were also made into or under the periosteum. The venous hæmorrhage was considerable, and seemed to wash the cocaine out of the tissues into which it had been injected. On this account, or in consequence of being obliged to use a weaker solution, and one not freshly made, the anæsthesia was not so profound or so enduring as in the previous operation. A longitudinal incision through the periosteum did not cause the patient any pain, but, when the periosteum was peeled off from the bone, the pain experienced was considerable. Section of the bone below the great trochanter with the electro-osteotome was without pain. Upon removal of the bone, the head and most of the neck of the femur were found to have been destroyed by disease. The acetabulum did not appear to be involved. The wound was closed with strong catgut sutures, drainage-tubes having been previously introduced, antiseptic dressings were placed over the line of suture, and a gutta-percha splint was molded to the contour of the limb and body, and allowed to harden.

105 Madison Avenue.

Book Notices.

Minor Surgical Gynæcology. A Treatise of Uterine Diagnosis and the Lesser Technicalities of Gynæcological Practice, including General Rules for Gynæcological Operations and the Operations for Lacerated Cervix and Perinæum and Prolapsus of Uterus and Vagina, for the Use of the Advanced Student and General Practitioner. By Paul F. Mundé, M. D., Professor of Gynæcology at the New York Polyclinic and at Dartmouth College, Gynæcologist to Mount Sinai Hospital, etc. Second Edition, Revised and Enlarged, with three hundred and twenty-one illustrations. New York: William Wood & Co., 1885. Pp. xxii-552.

(*First Notice.*)

We are glad to welcome a second edition of this excellent book, which now appears in a form more worthy of it. The author was very happy in the original idea of his manual, since

he wisely confined himself to just those minor technicalities which had been previously described in a most imperfect manner by the writers of more ambitious treatises. The real practical value of the book was at once apparent on comparing it with even such manuals as Chrobak's. It was, in a word, the difference between pure didactic construction and object-lessons. Not to dwell at length upon the reasons for the popularity attained by Dr. Mundé's work on its first appearance, it will be safe to assume that the present edition possesses additional claims to the reader's esteem. Part III is entirely new, while Part I and Part II have been carefully revised, and contain a considerable amount of fresh matter and several new illustrations. "Many cuts of instruments," as is aptly stated in the preface, "have been omitted for æsthetic reasons." It will be impossible, in the brief space allotted to us, to review critically the minor improvements of the new edition; but a glance at the more important points will serve to indicate the general scope of the volume.

In the section on the vaginal touch several new paragraphs will be noted, while Figs. 14 to 20, inclusive, have been added. Figs. 21 to 28, inclusive, also bear the author's initials, and are worthy of commendation. Pages 66 and 67, which describe the disinfection of instruments, contain most valuable advice with regard to an important subject which is too often overlooked by general practitioners, and, indeed, by not a few specialists, who are either too careless or too "conservative" to employ the simple precautions here given. One thing is certain: there would be a far smaller number of unfortunate results following gynæcological manipulations if the routine practice suggested by Dr. Mundé was more general. The omission of the usual confusing array of specula will be remarked as a decided improvement, while the additions to the section on holding the speculum (pages 85 to 91), including the excellent illustration (Fig. 45), must render the subject perfectly clear even to one who had never seen Sims's instrument in use—a condition of ignorance which is happily rare in these days of post-graduate instruction. Among the new paragraphs in the section which describe the use of the sound we note with approval the author's emphatic statement that this instrument is to be used *to confirm, and not as a substitute for, the bimanual examination.* Due stress is laid upon the dangers and contra-indications. Traction upon the uterus is deservedly reprehended as a pure diagnostic aid.

Part II, including pages 127 to 409, has received a thorough revision, but the interpolations are only apparent after a careful comparison of the two editions page by page. There are several new illustrations, some of which it must be confessed are not so clear as they might be (see page 220). The process of dilating the cervical canal, both by the bloodless method and by discission, is thoroughly described, and the advantages and disadvantages of each are fairly stated. The long and valuable section on pessaries has not been essentially altered. There are still rather too many illustrations for practical use.

Part III, on "Gynæcological Operations," being the new portion of the book, merits a careful examination. Under the head of "General Considerations" the author discusses the time of operating, the treatment of patients before and after operations, and the different varieties of sutures, disinfection, and anæsthetics. These pages will be of great value to the inexperienced operator, since they furnish just that information which his less fortunate predecessors have been able to acquire only by a long apprenticeship. Although no new facts are brought forward, the old ones are arranged in a compact, yet most readable, form. Nearly fifty pages are devoted to the operation of trachelorrhaphy, so that we are safe in assuming that the subject has been treated exhaustively. This otherwise excellent chapter is marred by the presence of a number of cuts which rather suggest, than actually illustrate, the conditions which they are intended to portray. To the experienced reader they are sufficiently clear, but, as works of art, Figs. 233 to 244, inclusive, are not lovely to look upon. The fault certainly does not lie with either the author or the artist, and the former deserves praise for his attempt to emancipate himself from the custom of copying the old cuts that have gone the rounds of all the text-books.

The Climate of Canada, and its Relations to Life and Health. By W. H. Hingston, M. D., D. C. L., L. R. C. S. Edin., etc. Montreal: Dawson Brothers, 1884. Pp. 266.

The author gives us, in this scholarly production, the result of many years' interest in and study of the climate of Canada. The nucleus for his essay was a discourse delivered before the Natural History Society of Montreal several years ago. Thi has been added to from time to time as relevant material came to hand, resulting in a book which retains the familiar colloquial style, and contains considerable matter which would not, perhaps, have appeared in a complete homogeneous essay on the subject, which Dr. Hingston expressly states this is not. He has succeeded, however—in the chapters on Climate proper, the Relations of this Climate to Health and Life, and on the Habits of the People—in giving us much new and valuable information about the country.

A short Introduction is given for the benefit of those who are not familiar with the constituents of climate and their effects on the human economy.

We learn from a study of Part I that, while there is great variety in different regions of the country, the climate as a whole may be set down as belonging to the dry, stimulating class—one especially adapted for a residence to those with a tendency to consumption, or in whom early signs of pulmonary disease have already developed.

On turning to Part II to obtain the author's *opinion* of the effect of the climate on mortality and disease (for statistical information is scant), we fall upon the opinions of an enthusiastic friend to whose sensation heat is never so hot, or cold so cold, in Canada as anywhere else, and by whom any deterioration in the people, or relatively great mortality (as in young children), is charged entirely to the habits of the people themselves. Unfortunately, as we have said above, accurate statistical information is wanting even of causes of death, except that which is furnished by the surgeons at the army stations, which makes a very favorable exhibit compared with that of the British stations. Fevers are, as a rule, mild, especially those of malarial origin. In regard to consumption, the army statistics support the modern theory of the superiority of a cold, dry climate over a warm, moist one for those predisposed to it, showing that Bermuda has 8·9 cases of it to 1,000 of mean strength of the army there, while Canada has only 5·6. According to the author's experience, affections of the skin are less frequent here than elsewhere; cataract is more common, but, nevertheless, blindness much less frequent. Scrofulous inflammation, so common a cause of blindness in Europe, is rare here. Blindness in Canada is commonly caused by small-pox, cataract, or injury. Contagious diseases—such as small-pox, measles, and whooping-cough—are more common than in Europe, especially in winter, when fuel is saved at the expense of ventilation. In the whole of Canada the proportion of the insane is one to seven hundred and twenty. In speaking of seasons, Dr. Hingston notices that the mortality commonly diminishes with the temperature, and that the colder parts of the country are in reality the more wholesome. The closing chapter—on the habits of the people in regard to eating, drinking, clothing, etc.—shows such a

bad condition of things, in the author's judgment, that it is certainly wonderful he is still able to maintain, as he does, that there is no evident deterioration of the European physique in Canada. At least a table of contents, but, better, a table of contents and index, should be added to another edition.

Clinical Lectures on Scrofulous Neck. By T. Clifford Allbutt, M. A., M. D. Cantab., F. R. S., F. R. C. P. And on *The Surgery of Scrofulous Glands.* By T. Pridgin Teale, M. A., M. B. Oxon., F. R. C. S. London: J. & A. Churchill, 1885. Pp. 32.

These two clinical lectures on scrofulous glands of the neck—one by a well-known physician, the other by a practical surgeon, the one treating of their cause and dangers to health, the other dealing with their surgical treatment—are well worthy of careful study. Dr. Allbutt insists upon the secondary nature of the enlargement of these glands of the neck, and considers that, in the vast majority of cases, the irritation, which is the cause, has its starting-point in a pathological condition of the mucous membrane of the pharynx, nose, or ear; that when once this increase in the size of the glands begins it is apt to go on to caseation, and adhesions form between the capsule and the gland, and also between the former and the surrounding tissues of the neck, terminating in the formation of an abscess; that, when once suppuration has taken place, it will undermine and perforate the skin and leave sinuses, which will continue to discharge until the diseased gland has been entirely eradicated.

He is very skeptical in regard to the spontaneous subsidence of these swellings, if the gland has attained much increase in size, as caseous matter has in all probability formed, and suppuration will take place. Medical treatment is of little use. When, however, the enlargement is not great and caseation has not taken place, much can be done by general constitutional treatment and a residence by the sea. He considers that after one is satisfied that cheesy matter has formed, the time for surgical interference has been reached, and that extirpation of the diseased gland or glands is called for.

Mr. Teale in his portion of the book treats of the surgical management of these enlarged glands. He advocates their removal by cutting down upon the gland and shelling it out of its capsule, if the latter has not become incorporated with the gland, and if the former has not become entirely degenerated. For, if this state has been reached, suppuration is almost inevitable, the skin will become undermined, sinuses form, there is great danger of other glands becoming involved, and disfiguring scars result. When abscesses have formed he advocates enucleating the diseased gland with a "spoon" and scraping the sinus. By these means the cause of the abscess is removed if pus has not formed, and, if suppuration has taken place, limits its duration and amount. In the former case the scar left after the operation is represented by a line, and in the latter case is much less noticeable than where the suppuration has been allowed to go on.

The volume is a practical and useful one, and should be generally read.

BOOKS AND PAMPHLETS RECEIVED.

A Text-Book of Pharmacology, Therapeutics, and Materia Medica. By T. Lauder Brunton, M. D., D. Sc., F. R. S., F. R. C. P., Assistant Physician and Lecturer on Materia Medica at St. Bartholomew's Hospital, etc. Adapted to the United States Pharmacopœia by Francis H. Williams, M. D., Boston. Philadelphia: Lea Brothers & Co. Pp. 1035.

A Text-Book of Medical Chemistry, for Medical and Pharmaceutical Students and Practitioners. By Elias M. Bartley, M. D., Adjunct Professor of Chemistry, etc., in Long Island College Hospital, etc. With Forty Illustrations. Philadelphia: P. Blakiston, Son, & Co., 1885. Pp. 376. [Price, $2.50.]

Milk Analysis and Infant Feeding. A Practical Treatise on the Examination of Human and Cows' Milk, Cream, Condensed Milk, etc., and Directions as to the Diet of Young Infants. By Arthur V. Meigs, M. D., Physician to the Pennsylvania Hospital and to the Children's Hospital, etc. Philadelphia: P. Blakiston, Son, & Co., 1885. Pp. 102. [Price, $1.]

De l'emploi du chlorhydrate de cocaïne dans le traitement de la coqueluche. Par le Docteur Moncorvo, professeur de clinique des maladies de l'enfance à la Policlinique de Rio de Janeiro, etc. [Extrait de "l'União Medica."]

Correspondence.

LETTER FROM WASHINGTON.

The Coming Meeting of the American Public Health Association.—Sanitary Inspection on the Canadian Border.

Washington, *October 20, 1885.*

Arrangements are being made for the meeting of the American Public Health Association, to be held here in December next. It is thought that by the earlier date of the meetings heretofore held much of the influence that would otherwise have been extended to legislative circles has been dissipated, but that a meeting during the opening week of the session of Congress, when the members are all here, will be much more effective in securing such legislation as is thought necessary. Dr. Toner and the health officer called on the President this week, and, it is said, secured from him a promise that he would be present at the opening exercises of the association. The "Conference" of health officers will take place at some time during the meeting, and, as they are the ones directly interested in the practical execution of State and local health laws, they naturally exert a much greater influence upon Congress than the association itself.

The revival of the Quarantine Act of 1878 has given the Government the only authority it has had in the management of national quarantine, since the expiration by limitation of the act of June 2, 1879, which substituted the National Board of Health for the Surgeon-General of the Marine-Hospital Service. Under the act mentioned it is possible to have a pretty strict land or sea quarantine at any place where the States have made no provision for it. There is now an inspection service organized along the Canadian frontier which will no doubt prove equal to the emergency. Michigan and New Hampshire are managing their own inspections—all, however, in harmony with the Marine-Hospital Service—but the States of Vermont, Maine, Massachusetts, and New York, through their respective governors, asked the Government to establish the service. Surgeon H. W. Austin, of the Marine-Hospital Service, has had immediate charge of the work on the frontier. The inspections, however, were apparently begun too late to insure absolute safety, although great good is done by the systematic vaccinations now for the first time imposed on travelers crossing our Northern border.

Work is progressing on the new Medical Library building foundations; the excavation is complete and the concrete is being filled into the trenches preparatory to laying the stonework.

A meeting of the local Committee of Arrangements of the International Medical Congress was held at Dr. Garnett's office last week. Nothing transpired of public interest.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.
Published by D Appleton & Co.
Edited by Frank P. Foster, M. D.

NEW YORK, SATURDAY, OCTOBER 24, 1885.

THE GOVERNOR OF NEW YORK AND THE STATE BOARD OF HEALTH.

We lately charged that the Governor of the State of New York was directly responsible for the attitude that we presumed the State would be obliged to take in asking aid from the General Government in the task of preventing an extension of the Canadian small-pox epidemic over the border. It has now transpired that such aid has been asked for by the State, and therefore the State is now depending upon the General Government to do for it what it would have been amply able to do for itself, but for the Governor's action in vetoing the appropriation of the moderate sum of fifteen thousand dollars made by the Legislature for the use of the State Board of Health.

Some of the newspapers, recognizing the awkwardness of the situation, have endeavored to palliate the Governor's course by making it appear that he simply vetoed an appropriation intended to cover a deficiency, that he pursued that course in consequence of his having discovered that there was really no such deficiency as had been alleged, and that the current impression concerning the veto is the result of misrepresentation.

In answer to all this, we have simply to remark that, long before the Legislature took any action in the matter, a document signed by all the members of the State Board of Health was submitted to Mr. Hill, setting forth the financial needs of the board in the following terms:

"As will be seen by reference to the report of the Executive and Finance Committee, the expenses of the board during the past fiscal year have exceeded the amount of its appropriation, the sum voted by the Legislature for the prosecution of its work being but $20,000, while the actual expenditures foot up to $21,971.36. Fortunately, an unexpended balance to its credit at the beginning of its last fiscal year enabled the board to discharge its obligations without incurring indebtedness; but the large growth of its registration work and the unprecedented demand for its engineering and sanitary counsel warn the board of threatened financial embarrassment during the coming year unless the $20,000 granted by the last Legislature for the continuance of its work is supplemented by a suitable subsidy in the supply bill. Urgent appeals are frequently received from local boards of health and citizens of various parts of the State for advice and assistance in questions of supreme moment to public health, requiring for their elucidation skilled sanitary inspection and often exact analytical examination. As far as the pecuniary resources of the State Board have permitted, prompt response has been made to such appeals; but, as they increase in number, lack of means compels reluctant neglect of some of them. Furthermore, under the duties imposed upon the board, to 'make inquiries in respect to the causes of disease, and especially of epidemics, and investigate the sources of mortality, and the effects of localities, employments, and other conditions upon the public health,' it is evident that a system of sanitary investigation was contemplated far beyond the present possibility of attainment, but absolutely needful to enable it to take 'cognizance of the interests of health and life among the people of the State.' Toward the fulfillment of these, the most important duties of the board, the sum of $15,000 is asked, and even with this, in view of a threatened epidemic visitation, the demands upon the board during the coming year will probably exceed its powers of compliance. The regular appropriation of $20,000 barely suffices to defray the expenses incident to the reception, recording, filing, and indexing of the State vital statistics at the central office, together with the voluminous correspondence necessitated by the wide range of questions constantly referred for reply."

It was in consideration of these facts that the appropriation was asked for, and the document from which we have quoted was transmitted by the Governor to the Legislature. The Ways and Means Committee granted the $15,000 asked for, and it was the committee's wording—not the Board of Health's—that made the item in the Supply Bill read for "deficiency." But the fact that the word "deficiency" did so appear now serves as the technical quibble on which the veto is sought to be justified; because, forsooth, the Comptroller's books do not show any balance on the wrong side of the account. Of course, the Comptroller will not pay anything in excess of the sum actually in his hands, so that there can never be a "deficiency" shown on his ledgers. It is puerile, therefore, for the Governor's apologists to urge that the State Board of Health asked for an appropriation to cover a deficiency, and that the non-existence of any deficiency was the Governor's reason for vetoing the bill. The Governor knew perfectly well at the time that he was depriving the board of money which it sorely needed to enable it to carry on the work that it was its duty to carry on; he knew, too, that, if the board had had a million dollars at its disposal, it could not legally spend more than $5,000 in any one year for sanitary inspection. When we add to this restriction the fact that another veto—that of the appropriation for the State survey—has deprived the Board of Health of the gratuitous services of Mr. Gardner, who, as director of the survey, was *ex-officio* a member of the board, in consequence of which the board has had to set apart $3,000 out of its $5,000 for engineering work imposed upon it in various acts passed by the last Legislature—when we take these facts into consideration, the full measure of Mr. Hill's blow at sanitation may be imagined.

THE PROPOSED NEW NATIONAL MEDICAL SOCIETY.

The plan of which we gave an outline some weeks ago, being that of a correspondent who had devoted a good deal of thought to the subject, and had found that it commended itself to a number of the leading members of the profession before whom he had laid it, has been favorably spoken of by several of our contemporaries, some of which have suggested modifications that are certainly worthy of consideration.

One of the suggestions thus brought forward is to the effect that an excellent society might be formed by the simple amalgamation of the various national special societies that now exist. The obvious objection to this is, that the general practitioners would not be represented, and it is undeniable that they include,

and always will include, a large proportion of the strong men of the profession. Except for work in a special line, no organization that leaves out the general practitioner can become of much consequence to the profession as a whole. We doubt if the suggestion was seriously intended, but it is one that has been made before, and therefore is worthy of notice, although, we think, only to be rejected.

The "Medical Record" approves of our correspondent's plan in the main, but thinks that, unmodified, it would not be sufficiently "democratic." We presume that by this our contemporary means that it would not be representative in the geographical sense. Our own idea is that it ought not to be. A strictly regional representation is of consequence only where legislation is involved, and the less legislation the new society attempts, or is designed to attempt, the better. We are just now suffering from too much legislation. Does any one suppose that the Royal Society and the French Academy fail to "represent" the learning and the culture of Great Britain and France? Yet the geographical notion, we fancy, would be scouted by both of them. The "deestrick" system has never yet led to anything very high-minded.

Nevertheless, the geographical idea may prove tolerable in this instance, provided it is hedged about by certain safeguards, and, if it should prove to be dear to the great majority of American physicians, we should not oppose it; neither, we suppose, would our correspondent.

MINOR PARAGRAPHS.

INTERNATIONAL COLLECTIVE INVESTIGATION.

We have received a very carefully prepared pamphlet designed for the guidance of individual observers in the work of the collective investigation of disease set on foot at the last meeting of the International Medical Congress. The pamphlet deals with rickets, acute rheumatism, chorea, cancer, and urinary calculus, and contains blank forms, which those who receive them are asked to fill out and return to Dr. Jacobi, one of the American members of the Congress's committee on the subject, the other being Dr. N. S. Davis.

The pamphlet is interesting in itself, and doubly interesting as suggesting the query, How can the undisputed holder of an official position under the Congress—and Dr. Jacobi is undoubtedly to be so reckoned—be looked upon as having been ineligible to any office the committee charged with organizing the ninth Congress saw fit to confer upon him? Yet that is precisely the illogical position that the New Orleans meeting of the American Medical Association took when it virtually instructed its enlarged committee to displace him from the organization as it then stood.

AN "INDORSEMENT" OFFERED FOR SALE.

In another column we publish a letter from Dr. W. Oliver Moore, calling attention to an injustice that certain competing pharmacists have practiced toward Messrs. Mariani & Co. in "pirating" published records of the successful use of the Mariani preparations of coca, and at the same time craftily making those records appear to apply to their own preparations. It is very much to be regretted that a house that has been so punctilious in avoiding even the semblance of any offense against the courtesy of trade should have been treated in this shabby way by some rival manufacturers. It is still more to be regretted, however, that a member of our own profession should have shown such a willingness to exchange his "indorsement" of the Vin Mariani for money, as is apparent in a letter lately received by Messrs. Mariani & Co., from which we quote as follows:

"Will you kindly favor me with four (4) copies of your essay on 'Erythroxylon Coca,' and oblige? If you will refer to the 'Med. Record' for ....., advertising page vi, you will see me quoted by ——— & Co. for indorsement of fl. ext. coca. That is indeed a very good preparation, but your *Vin Mariani* is *very fine*. If we have the cholera, I should give it as a leading tonic. If my indorsement, *as the first user of coca in the U. S.*, will advantage you any for advertising purposes, I will furnish it to you for $25. If, also, you will honor me with some samples of your Pâte Mariani, you will oblige."

It is consolatory to know that the firm in question looked upon this bit of impudence as quite phenomenal. We would advise this "first user of coca" to keep on using it—upon himself—in the hope of ultimately raising himself above pseudo-scientific mendicancy.

THE PENNSYLVANIA STATE BOARD OF HEALTH.

The State of Pennsylvania has been somewhat tardy in establishing a State board of health, but perhaps she has only been making haste slowly. Quite likely, this fact has not been altogether to her disadvantage. At all events, she has constituted her first board, as we learn by a recently published "Address of the State Board of Health and Vital Statistics of the Commonwealth of Pennsylvania to the People of Pennsylvania," almost entirely of medical men, the single exception being that one member of the board is an engineer. We at once recognize the value of an engineer in the board, but we have always been at a loss to estimate the precise advantage of having broken-down "statesmen" or political "workers" in such positions. The board's "Address," to which we have alluded, is a remarkably simple and cogent exhortation to the people of the State to further the work of the board in their own behalf, quite free from the cant that so often figures in such documents. It must be said that the new board seems to be entering upon its work in a most commendable spirit, and we wish it the fullest measure of success.

THE PROFESSION OVER-CROWDED ABROAD.

Much having been written about the over-crowding of the ranks of the medical profession in this country, some dreary consolation may be drawn from the state of things that is represented to prevail in at least two foreign countries, one of which is even newer than our own. It seems from a recent article in the "Lancet" that the repletion of the ranks has lately been made the subject of serious inquiry by a medical society in Belgium. It appears that certain "specialists" are allowed to practice in that country without having taken a medical degree, and the complaint is made that the preliminary examination is not severe enough.

The other country referred to is Australia, from which a member of the British Medical Association writes a long letter to the "British Medical Journal," complaining of the enormous difficulties in the way of success in practice. He says that at Ballarat there are more medical men to-day than there were when the population was greater by fifteen hundred.

NEWS ITEMS, ETC.

The New York Obstetrical Society.—At the annual meeting, held October 20th, officers were elected as follows: Dr. Paul F. Mundé, president; Dr. H. T. Hanks, first vice-president; Dr. Louis A. Rodenstein, second vice-president; Dr.

Henry C. Coe, recording secretary; Dr. Emil Noeggerath, corresponding secretary; Dr. Edward L. Partridge, treasurer; Dr. James B. Hunter, pathologist; Dr. Colin Mackenzie, Dr. Bache McE. Emmet, and Dr. Clement Cleveland, members of the committee on admissions (to hold office from 1885 to 1887, acting in conjunction with Dr. Robert Watts, Dr. H. T. Hanks, and Dr. J. B. Hunter, who continue in office until 1886).

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the three weeks ending October 20, 1885:

DISEASES.	2 weeks ending Oct. 6.		Week ending Oct. 20.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	2	1	3	1
Typhoid fever	78	16	33	12
Scarlet fever	40	3	21	3
Cerebro-spinal meningitis	2	2	4	4
Measles	6	1	6	0
Diphtheria	79	33	53	22
Small-pox	11	0	1	1

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, October 7th: *Montreal, Canada.*—October 1st to 13th: 391 deaths from small-pox, in the city, and 101 deaths in adjacent municipalities. *Kingston, Canada.*—October 2d: Free from epidemic diseases. *Three Rivers, Canada.*—For the week ending October 10th: 6 cases and 2 deaths from small-pox. *Toronto, Canada.*—For the week ending October 10th: 1 case of small-pox reported; 3 cases are now being treated in hospital. *Havana, Cuba.*—For the week ending October 8th: 20 cases and 10 deaths from yellow fever. *Cardenas, Cuba*, September 26th; *Matanzas, Cuba*, October 7th; *St. Thomas*, October 2d; *San Domingo*, September 28th, and *Cape Haytien, Hayti*, September 26th: All free from epidemic diseases. *Acapulco, Mexico.*—For the week ending September 27th: 4 deaths from yellow fever. *Guaymas, Mexico.*—For the month of September: 200 cases and 47 deaths from yellow fever; 26 of the deaths were among officers and soldiers. *Callao, Peru.*—September 5th: 1 death from small-pox. Yellow fever has disappeared. *La Guayra, Venezuela.*—For the week ending September 12th: Free from epidemic diseases. Yellow fever is, however, prevalent and fatal at *Caracas. Buenos Ayres.*—For the months of July and August: 205 deaths from small-pox. *London, England.*—For the three weeks ending October 3d: 15 deaths from small-pox. *Glasgow, Scotland.* For the week ending October 3d: 1 death from small-pox. *Edinburgh, Scotland.*—For the week ending September 12th: 1 death from small-pox. *Bradford, England.*—September 19th: 1 case of small-pox reported. *Paris, France.*—September 26th to October 8th: 4 deaths from small-pox. *Bordeaux, France.*—For the week ending October 3d: 2 deaths from small-pox. *Antwerp, Belgium.*—For the week ending October 3d: 2 deaths from small-pox. *Barcelona, Spain.*—From September 10th to 20th: 425 cases and 170 deaths from cholera; also 1 case of small-pox reported. Cholera is abating and assuming a milder form in all the districts. *Cadiz, Spain.*—September 19th: Total mortality during the week, 186. Average mortality, 40. The excess is attributed to cholera. September 26th: 118 deaths from cholera during the week. *Valencia, Spain.*—September 19th: 3 cases and 1 death from cholera. The port (Grao) of Valencia is now supposed to be free from cholera. *Gibraltar, Spain.*—For the week ending September 27th: 2 cases and 2 deaths from cholera. From August 1st to date of report there had been 24 cases and 19 deaths from cholera. October 4th: No new cases of cholera within the past eleven days. *Tarragona, Spain.*—From September 1st to 28th: 75 cases and 37 deaths from cholera. No new cases reported since the 24th. *Genoa, Italy.*—From September 20th to October 4th: 5 cases and 2 deaths from small-pox. *Venice, Italy.*—From September 5th to 19th: 17 cases of small-pox. *Trieste, Austria.*—From September 2d to 26th: 23 cases and 6 deaths from small-pox. *Prague, Bohemia.*—September 24th: 1 death from small-pox. *Zurich, Switzerland.*—From September 12th to 30th: 2 deaths from small-pox. *Warsaw, Russia.*—From September 12th to 26th: 5 cases and 4 deaths from small-pox. *Calcutta, India.*—From August 2d to September 5th: 19 deaths from cholera. *Jerusalem, Palestine.*—For the months of May, June, and July: Small-pox reported prevalent. *Colombo, Ceylon.*—August 15th: 34 cases and 24 deaths from cholera reported.

The following is the number of cases and deaths from cholera in Spain, from March 4th to September 17th, inclusive: 259,684 cases and 96,094 deaths. In Italy, from August 4th to September 13th, there were 165 cases and 89 deaths from cholera.

The Washington Obstetrical and Gynæcological Society.—At the annual meeting, held on the 16th inst., officers were elected for the ensuing year as follows: Dr. A. F. A. King, president; Dr. W. W. Johnston and Dr. J. Taber Johnson, vice-presidents; Dr. C. H. A. Kleinschmidt, recording secetary; Dr. S. S. Adams, corresponding secretary; Dr. G. B. Harrison, treasurer; Dr. C. F. Hagner, Dr. L. Tyler, and Dr. Adams, committee on business; Dr. G. N. Acker, Dr. H. H. Barker, and Dr. H. D. Fry, committee on admissions; Dr. T. C. Smith, Dr. J. R. Bramwell, and Dr. Kleinschmidt, committee on publicaton; and Dr. Acker, Dr. G. W. Johnston, and Dr. Harrison, committee on pathological specimens.

The New York Academy of Medicine.—A special meeting was held on Monday evening, the 19th inst., for the purpose of founding a section in ophthalmology and otology. Dr. C. R. Agnew was chosen president, and Dr. J. A. Andrews secretary. The meetings will be held on the third Monday of each month, excepting July, August, and September.

The late Professor Charles Robin is thus spoken of by the Paris correspondent of the London "Medical Times and Gazette": "The history of Professor Robin was for a long space of time the history of medical microscopy itself, and he stood prominent as the representative of that branch of study in opposition to Velpeau and other practical and clinical teachers, who endeavored to cast ridicule upon the microscope and histology as viewed in relation to medical science. The triumph of Robin appeared complete when, in 1861, a chair of histology was created at the Faculty of Medicine, of which he became, of course, the first occupant. His success was great at first, but he soon became unpopular with the students on account of his extreme severity as an examiner; while, on the other hand, the clerical party, then predominant, were incensed at the so-called materialistic tendencies of his lectures and writings. The combination of these two hostile forces led to violent scenes, in which the professor was hissed, abused, and prevented from speaking. At a later period he regained his popularity through the petty persecutions of the clerical party, which, among other annoyances, excluded him from the list of persons qualified to sit upon a jury, although at this time Robin was unquestionably one of the most celebrated men of science in Europe. He had become, in spite of strenuous opposition, a member of the Institute in 1866. When the Senate was created in 1870, Robin was named a Senator by his native department (Ain). He re-

mained a member of the Assembly till his death, although in politics, like many scientific and literary celebrities, he was content to play a dumb part. Indeed, both his qualities and defects made him unfit to play the part of a Demosthenes; he had neither the eloquence nor the assurance which are the stamps of the political orator, and which are seldom developed by a severe process of scientific training. Robin was one of the chief disciples of Auguste Comte, and one of the founders of the celebrated *Société de biologie*, along with his intimate friend, Claude Bernard. He was also closely connected with Littré, and became with him one of the joint editors of the *Dictionnaire de Nysten*, which, although in the beginning a mere vocabulary of words employed in medical science, became a stumbling-block to orthodox believers and a sort of gospel to the followers of positivism, through the extreme boldness of some of its definitions, those, for instance, of *Ame*, *Homme*, and a few others of the same description. In private life Robin was a most amiable and disinterested man. All his pupils were much attached to him, and he will be sincerely regretted by his numerous friends."

Obituary Notes.—The death of Dr. William Workman, of Worcester, Mass., took place on Saturday, October 17th, in the eighty-seventh year of his age. He was born in Colerain, Mass., was graduated from Harvard Medical School in 1825, and became a member of the Massachusetts Medical Society in 1831. After practicing in Shrewsbury, Mass., for ten years, in 1835, he settled in Worcester, where he has since resided. He was for ten years a trustee of the Worcester State Lunatic Hospital.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department United States Army, from October 11 to October 17, 1885:*

Irwin, B. J. D., Lieutenant-Colonel and Assistant Medical Purveyor. Ordered from Department of Arizona to New York city for temporary duty in charge of Medical Purveying Depot at that place, relieving Captain Henry Johnson, Medical Storekeeper. S. O. 233, A. G. O., October 10, 1885.

Morris, Edward R., First Lieutenant and Assistant Surgeon (recently appointed). Ordered for duty in Department of the Missouri. S. O. 233, A. G. O., October 10, 1885.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending October 17, 1885.*

Baldwin, L. B., Passed Assistant Surgeon. Detached from Naval Hospital, Philadelphia, and ordered to Navy-Yard, Mare Island.

Dickinson, D., Surgeon. Detached from Naval Hospital, Mare Island, and ordered to Training Ship Portsmouth as relief to Surgeon A. M. Moore.

Moore, A. M., Surgeon. Detached from Training Ship Portsmouth, and to await orders.

Shafer, Joseph, Assistant Surgeon. Detached from Receiving Ship St. Louis, and ordered to Naval Hospital, Philadelphia, as relief of Passed Assistant Surgeon Baldwin.

Hester, F. A., Assistant Surgeon. Detached from U. S. S. Minnesota, and ordered to the Tennessee as relief of Passed Assistant Surgeon Nelson H. Drake.

Drake, Nelson H., Passed Assistant Surgeon. Detached from the Tennessee 31st inst., and to await orders.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the week ended October 10, 1885.*

Bailhache, P. H., Surgeon. To proceed to Tuckerton, N. J., as inspector. October 7, 1885.

Austin, H. W., Surgeon. To proceed to Albany, N. Y., on special duty. October 6, 1885.

Gassaway, J. M., Surgeon. To examine surfmen at Ellsworth, Me., and other ports of First District Life-Saving Service. October 9, 1885.

Society Meetings for the Coming Week:

Monday, *October 26th:* Medical Society of the County of New York; Boston Society for Medical Improvement; Lawrence, Mass., Medical Club (private); Cambridge, Mass., Society for Medical Improvement.

Tuesday, *October 27th:* New York Dermatological Society; New York Surgical Society; Buffalo Obstetrical Society (private); Medical Societies of the Counties of Putnam (quarterly), Queens (semi-annual—Garden City), and Rockland (semi-annual), N. Y.; Boston Society of Medical Sciences.

Wednesday, *October 28th:* New York Pathological Society; American Microscopical Society of the City of New York; Philadelphia County Medical Society (conversational); Auburn, N. Y., City Medical Association; Berkshire, Mass., District Medical Society (Pittsfield); Medical Society of Gloucester County, N. J. (quarterly); Middlesex, Mass., North District Medical Society (Lowell); American Academy of Medicine (New York—first day).

Thursday, *October 29th:* New York Orthopædic Society (at 214 East Thirty-fourth Street. Two or three short papers on "Rotary Lateral Curvature"); Cumberland County, Me., Medical Society (Portland); Massachusetts Medical Benevolent Society (annual); American Academy of Medicine (second day).

Letters to the Editor.

LACERATIONS OF THE CERVIX UTERI.

Jersey City, N. J.

To the Editor of the New York Medical Journal:

Sir: In your report of the proceedings of the Medical Society of Virginia, on the 10th inst., I noticed an abstract of a paper read by Dr. Bedford Brown, of Alexandria, on the "Treatment of Lacerations of the Os and Cervix Uteri without Surgical Operation." I read the same with great interest, and fully indorse the treatment he suggests. It has been followed by me for many years with excellent results. The graduated solutions of nitrate of silver, ℈j to ℈ij, and ʒj to 1 oz. of water, enable the physician to select the required strength adapted to the particular case. I have always used cotton on the end of an applicator, in preference to a camel's-hair brush, as it can be thrown away and a new piece used for each application; or, when there is enlargement of the cervix, I moisten or saturate the same with glycerin, which has the property of causing a serous discharge, and thereby tends to reduce the size of the cervix. When the cervix is large and indurated, I know of nothing equal to hot-water injections, once or twice a day, and continued until the desired results are obtained—softening and a return to the normal size. For this purpose I prefer the fountain syringe to any other I know of. I have lately finished the treatment of two patients who had suffered from lacerations of the os and cervix uteri. They were treated principally with the nitrate-of-silver solutions, Lugol's solution, hot-water injections, and occasionally scarifications of the cervix. Both entirely recovered.

James Craig, M. D.

RIVAL PREPARATIONS OF COCA.

133 East Thirty-eighth Street, N. Y., *October 14, 1885.*

To the Editor of the New York Medical Journal:

Sir: In your issue of January 3, 1885, page 19, in a report of a paper read before the New York Medical Society, on "The Physiological and Therapeutical Effects of the Coca-Leaf and its Alkaloids," occurs the following: "For the past ten years Dr. Fauvel has used it, both internally in the form of Vin Mariani, and also by local applications to the pharynx and larynx in spray or by brush, in the form of a fluid extract, or, more recently, of a concentrated non-alcoholic preparation more of the nature of a cordial (prepared by Mariani & Co.)."

Several manufacturers of coca preparations have taken occasion to quote from this paper, each in turn substituting the name of *his own* production instead of the one mentioned in the original.

As the preparations of coca mentioned in my paper were personally tested and found to be the best of a large number experimented with, I wish to call attention to these misquotations and substitutions.

Very truly, W. Oliver Moore.

*** We have taken the trouble to compare the report of Dr. Moore's remarks with the little book on coca prepared by M. Mariani, and the latter with the circulars issued by a number of manufacturers of coca preparations; and we certainly think that some of these manufacturers have taken an unwarrantable liberty in appropriating work that evidently cost M. Mariani a good deal of time and no little outlay of money.

Proceedings of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of October 14, 1885.

Dr. George F. Shrady, President *pro tem.*

Melano-Sarcoma of the Face.—Dr. John A. Wyeth presented a woman seventy years of age who showed the results of an operation for removal of a melano-sarcoma of the face. Fourteen years ago a small tumor appeared at the left of the nose, and remained nearly stationary for several years, after which it enlarged gradually. The integument alone seemed to be implicated. Four years ago it was burned with some escharotic. A short time ago Dr. Fox made a diagnosis of melano-sarcoma, and sent the patient to Dr. Wyeth for operation. Dr. Wyeth carried the incision from well up on the nose outward an inch and a half, and a quarter of an inch below the palpebral border. The gap was filled with integument drawn over the malar bone. The operation was done only two weeks ago, but perfect union existed at present and there was no ectropion.

A Cast of the Bladder.—Dr. H. J. Boldt presented a cast of the bladder of a woman aged eighteen years who had recently given birth to her first child. Delivery was normal. Soon afterward, September 21st, she complained of pain in the hypogastric and lumbar regions. There was tenderness on pressure. Micturition caused no pain. The urine contained albumin, blood-casts, and a small quantity of pus. The diagnosis was made of catarrhal nephritis. At this time the temperature was 102·6° F., but some days later it rose to 106°. The patient felt something in the urethra while urinating, and, on examination, Dr. Boldt thought the sac to be a portion of the inverted bladder. He replaced it, and did so several times subsequently. Dr. Lusk, who saw the patient in consultation, thought it to be an inversion of the bladder, and, as the presenting portion was becoming putrid, it was dusted with iodoform. Finally it was expelled and was found to be, as Dr. Boldt believed, the mucous membrane of the bladder with some submucous tissue and perhaps some of the muscular fibers. He had not examined it microscopically, and consequently wished that it be referred to the Microscopical Committee. After its expulsion, the bladder-walls seemed to be entirely denuded of their lining membrane, and became thickened, and the cavity greatly decreased in size. A large quantity of urine was passed during the twenty-four hours. The patient died, on the 10th of October, with cerebral symptoms, probably of a septic nature.

Large Sarcoma of the Ovary.—Dr. Cushier presented a sarcomatous tumor, probably of the ovary, as large as a bucket, removed post mortem. The patient, forty-nine years of age, otherwise healthy, had first noticed an enlargement of the abdomen about a year previously; the increase in size was then very rapid. Her health had become greatly impaired when she was seen by Dr. Cushier. Dr. Hunter saw her in consultation, and an exploratory incision was made, but the operation was discontinued. The patient died on the fifth day afterward, probably of disappointment at not having the tumor removed, and of exhaustion. There was found to be slight red hepatization of the left lung, with some pulmonary nodules of the nature of the abdominal tumor, and nodules in the retro-peritoneal glands. The tumor involved the left ovary and the uterus, and was pronounced to be a spindle-and-round-celled sarcoma, probably originating in the ovary, the more common origin of such growths.

Dermoid Cyst of the Ovary.—Dr. Cushier also presented a dermoid cyst of the ovary removed last Thursday. It had been of comparatively rapid growth. There was some elevation of the temperature prior to the operation. Adhesions existed throughout, but were not firm. The larger cavity was filled principally with sebaceous material; only a small pouch was occupied by hair.

Congenital Cyanosis.—Dr. L. E. Holt presented the heart, lungs, and kidneys of a child which had died of congenital cyanosis, forty-eight hours after birth. There was a distinct syphilitic history; the child was born about the eighth month; it weighed between four pounds and four pounds and a half, and was cyanotic. The respiration was very rapid, and the pulse could not be counted. Examination of the lungs showed over both sides marked diminution in resonance and many fine râles. At the autopsy the lungs were found to be solid, did not crepitate at all, and sunk in water; it was difficult to find with the unaided eye any air cells which had been distended. The foramen ovale was sufficiently large to admit two fingers; the right ventricle was slightly thickened; there was no disease of the valves. The spleen was enlarged and hard, and showed venous congestion. Externally the kidneys were slightly softened; the cortex was quite pale, and the pyramids were somewhat congested, showing uric-acid infarctions. There was interstitial nephritis.

PHILADELPHIA PATHOLOGICAL SOCIETY.

Meeting of September 24, 1885.

The President, Dr. E. O. Shakespeare, in the Chair.

Tænia Echinococcus.—Dr. William Osler presented specimens of this rare parasite, which had been reared experimentally by feeding a dog with hydatids from the liver of a pig. The animal was killed about seven weeks after the feeding, and the small intestine was found to contain many hundreds of the ma-

ture tape-worms. The portion of bowel exhibited had many adherent to the mucous membrane. From the small size of the worms, only a few lines in length, they were very apt to be overlooked. Cobbold stated that the only specimens procured in England had been experimentally reared. Dr. Leidy had never met with the adult worm in this country. That it must occur here in the dog was very evident from the frequency with which echinococcus cysts (the larvæ) were met with in the hog and other animals.

Cysticercus Cellulosæ.—Dr. Osler exhibited the heart, the brain, and a portion of the flesh of a pig, containing the "measles," as the larvæ of the *Tænia solium* were called. Both organs were thickly studded with the cysts, which were also very numerous throughout the muscular system. The animal was fat and had seemed to suffer very little inconvenience. Attention was called to the cysts beneath the tongue and to the possibility of telling whether an animal was measled by an examination of this part during life. Microscopic slides of the parasites were shown and a slide of a cysticercus, with a very large caudal vesicle, from the omentum, in which situation it might grow to the size of a walnut.

Distoma Hepaticum; its Effects on the Liver.—Dr. Osler also showed the liver of an ox, showing enormous enlargement of the bile-vessels and calcification of their walls, due to the chronic inflammation excited by the presence of the flukes. The main ducts were thicker than the thumb, and even the smaller tubes were as hard as the stem of a clay pipe. The liver substance was wasted but not cirrhotic. In spite of this extensive disease, the animal was well nourished. Specimens of the flukes in spirit and mounted were also shown.

Tænia Flavopunctata.—Dr. William Pepper presented the specimens of *Tænia flavopunctata* described by Prof. Leidy in the "American Journal of the Medical Sciences" for July, 1884. This species had never but once before been seen and recognized, and then by Weinland, of Boston, in 1858. Both specimens had been expelled from young children and averaged twelve inches in length.

Tænia Mediocanellata.—Dr. Pepper also presented the head and neck of a *Tænia mediocanellata*. It had occurred in a young man. A course of starving, followed by castor-oil and pelletierine, had removed a portion of the worm; afterward a repetition of the starving process, without the castor-oil but with the alkaloid, had brought away the entire worm dead. Dr. Pepper said he was particularly interested in this series; it spoke forcibly of the necessity of studying comparative pathology. The specimens were very perfect and more instructive than more highly organized species. In practice he had found the *Tænia mediocanellata* as difficult to expel as the *Tænia solium*. The exhibition of the small variety, the *Tænia flavopunctata*, taught the necessity of careful examination of the stools.

Litholapaxy.—Dr. de Schweinitz exhibited the kidneys, ureters, and bladder of a man who had died after this operation. The patient, aged seventy-three years, had for two years previous to the operation suffered with straining during the act of micturition and other symptoms of hypertrophy of the prostate gland, and of vesical calculus. The urine contained albumin, pus, epithelium, and granular casts, and had a specific gravity of 1·018. The patient's habits were intemperate. The operation of litholapaxy was performed, marked difficulty having been experienced in the introduction of the instruments. After the operation the patient exhibited great restlessness, præcordial pain, and a rapid, feeble pulse. Subsequently he became comatose, and died twenty hours after the operation, the immediate cause of death being, apparently, the formation of a heart-clot. A post-mortem examination was made about ten hours after death. Old pleuritic adhesions were found on the right side. The muscular structure of the heart was flabby; there was a firm "chicken-fat" clot in the right ventricle. The liver was slightly enlarged and soft. Both kidneys were granular and contained cysts. The bladder was thickened, and showed ecchymoses on its mucous surface. The prostate was enlarged.

Dr. Tyson thought this case added one more to the list showing the impropriety of crushing for stone when kidney disease was present. He did not know why, but under such circumstances the cutting operation was more suitable. He cited the case of Louis Napoleon as an instance of the danger of crushing in the presence of kidney disease. In answer to a question of Dr. Barton's regarding the kidneys, he said that they were contracted, though not decidedly so, as there was good secreting structure left. The cysts were part of the pathological anatomy of granular kidney. He believed the cause of death to have been uræmia.

Dr. G. G. Davis said that in such cases a post-mortem examination was in reality of the nature of an investigation. Death might be due to direct violence done the nrethra, the prostate, or the bladder; or it might be due to extension of inflammation to the peritonæum, or to some unknown cause, as in the present case.

Dr. de Schweinitz said that the urethra was not examined, and agreed with Dr. Tyson that the cause of death was uræmia. This was the more probable because an officious attendant, against orders, had administered rather full doses of morphine.

Syphilitic Abscess and Necrosis of the Tibia.—Dr. Henry Beates presented a specimen of syphilitic abscess and necrosis of the tibia removed by amputation at the middle of the thigh. The patient was a strumous man who three years previously had suffered from an attack of obstinate sciatica accompanied by a marked degree of muscular atrophy of the affected limb, followed by lameness. Two years later a swelling developed at the femoral side of the gluteo-femoral crease, which opened and discharged small fragments of necrosed bone. The sinus was finally healed and fair health enjoyed for several months. Seventeen weeks ago osteitis of the tibial head developed, followed, in a short time, by suppurative synovitis. The pus perforated the ligamentum posticum and burrowed beneath the gastrocnemius, elevating it and the posterior tibial muscular structures from the bone. Free incision evacuated this, but the destructive process continued, resulting in the formation of sinuses and complete disintegration of the joint. Hectic was pronounced, and, to save life, amputation was performed on the day previous. Longitudinal section through the femur, joint, and tibia disclosed the extensive destruction effected in so comparatively short a time. The articulating surface of the condyles was denuded of its cartilage and the surface of the bone was roughened. The patella was bound firmly to the trochlear portion of the condyles. The articular elements were destroyed. The head of the tibia was completely necrosed and broken down. The medullary canal of the tibia, throughout its entire extent, was infiltrated with pus. The surface of the bones was also the seat of the morbid process. The pus from the joint had burrowed upward beneath the internal and external vasti muscles and deprived the femur of its periosteum for a considerable distance. The anterior face of the tibia was denuded in like manner, while the crest, at the middle, was the seat of ulceration. At the time the disease occurred the patient first noticed a chancre. Six weeks later the secondary phenomena developed and were promptly met with anti-syphilitic remedies. Was the strumous disease influenced by the syphilis? The specimen was referred to the Committee on Morbid Growths for microscopical examination, with instructions to look for tubercle bacilli and for those said to be peculiar to syphilis.

Dr. Davis was desirous of knowing if the disease of the head of the tibia was due to scrofula or syphilis; the worm-eaten character of the ulcer on the tibia looked like syphilis.

Dr. C. M. Wilson inquired if there had been fever, rigors, and evidences of pyæmia in this case. It was undoubtedly one of osteo-myelitis, and in a similar case of traumatic origin, which he had exhibited, rigors had been present.

Dr. Jurist asked how the presence of acute syphilis in the patient would affect the prognosis of the operation.

Dr. Beates replied that there had been symptoms of septic fever, and, as the acute symptoms of syphilis had been absent for some weeks, he did not think this would affect the prognosis.

Sudden Death from Laryngeal Obstruction.—Dr. Louis Jurist presented the larynx and trachea removed post mortem from the body of man, aged thirty-eight, a book-keeper, who had suddenly died. He had not had syphilis. He had taken cold on Saturday and had a sore throat; on Tuesday he chatted with the doctor, and an examination gave no evidence of anything except ordinary pharyngitis; on Wednesday he went to his business; on the evening of this day the doctor was sent for in haste, and, on going at once, found the man dead. Nevertheless, a hurried laryngotomy was done, and efforts were made to restore the heart, but without avail. Dr. Jurist removed the larynx through the thoracic cavity. He was in doubt as to the mode of death. The lungs were fairly healthy, though cheesy on one side. There must have been an abscess present.

Dr. Tyson was surprised that marked improvement should have followed the treatment by emetics and sedatives, as the abscess must have been present; perhaps the outlying œdema was subdued and the condition thus improved.

Dr. Wharton had had no experience in such cases, but agreed with Dr. Jurist that the operation of tracheotomy, and not laryngotomy, was indicated.

Dr. Jurist was in doubt in regard to the diagnosis; it rested between perichondritis and a subsequent abscess or phlegmonous laryngitis. He was inclined to the former view.

BROOKLYN PATHOLOGICAL SOCIETY.

Meeting of May 14, 1885.

The President, Dr. B. F. Westbrook, in the Chair;

Dr. A. H. P. Leuf, Secretary.

Pulmonary Abscess and Pyæmia.—Dr. Glentworth R. Butler read an account of a case, for Dr. Lewis S. Piloher. [It was reserved for publication.]

A Cranio-rhachitic Monster with Exomphalos was shown by Dr. W. J. Brandt.

Valvular Aneurysm.—A paper with this title was read by Dr. Albert Brinkman. [See page 455.]

Pulmonary Miliary Tuberculosis.—A fresh specimen was shown by Dr. A. H. P. Leuf.

Meeting of June 11, 1885.

Intra-capsular Fracture of the Femoral Neck.—Dr. J. H. Hunt presented a specimen of this kind, in which there had been an impaction of the neck into, and the formation of a false joint within, the great trochanter.

The President considered it a remarkable case because of the site of the false joint.

Dr. Z. T. Emery presented a specimen of the same injury, with a false joint.

Dr. Hunt remarked that it was peculiar in that there were fibrous connections, like so many chordæ tendineæ, between the false-joint surfaces in place of a ligamentum teres. He asked if it was possible for a heavy woman, as this one was, to have her hip give way spontaneously instead of its being due to violence.

The President could not account for the impaction except by violence. He questioned whether a spontaneous fracture could have caused the fall of the woman, and this, in turn, have given rise to the impaction.

Dr. Hunt rejoined that she was very intelligent and disclaimed having stumbled. There was no history of tripping. The fall seemed to be spontaneous. He simply desired to know whether it was possible that the fracture could have preceded and caused the fall and the latter the impaction. He hardly supposed it probable, but did not consider it impossible.

Acute Lepto-meningitis.—Dr. Arnold Stub read the history of a case as follows:

"A gentleman, thirty-seven years of age, of steady habits, whose former history gave no clew to any previous disease, and who for years past had no other complaint except an occasional severe neuralgic pain in the face, for which it seems, however, he never consulted a physician, returned from a theatre during a cold and stormy night (March 28th) at 11.30. It seems he went to bed perfectly well, but awoke at 2 A. M. (March 29th) and called the members of his family to his room, on account of a severe attack of vomiting he had been seized with. It seems he offered no explanation as to how he felt, but lay in bed constantly vomiting and moaning, and, upon being asked what ailed him, only said: 'It is awful.' It seems that his family thought he had been eating or drinking something unusual, and waited until morning before they sent for me. Upon my arrival, about 9 A. M., March 29th, I found him lying in bed, continually tossing about, smiling and grinning in a peculiar, almost idiotic manner, and talking at random. Upon being asked how he felt, he declared he felt all right, and had no pains, but he pointed toward his abdomen if the question was pressed. He still vomited occasionally. The pulse was 80 and, like the temperature, the heart's action, and the pupils, perfectly normal. Upon inquiry, I could not learn when he had urinated last. He certainly had not done so since 2 A. M. Percussion showed the bladder to be empty. The introduction of a catheter was impossible on account of his restlessness. I diagnosticated uræmia. Taking into consideration the entire absence of all symptoms tending toward brain trouble, his apparently empty bladder, the fact that he had been sitting in a hot, closely packed theatre, and afterward returned home during a snow-storm, I felt justified in coming to such a conclusion, and I ordered fifteen grains of calomel to be given at once, and, two hours afterward, one ounce of castor-oil, which he took and retained. I also ordered liq. ammonii acetatis, ʒ ij, every hour, and hot bran-bags to be applied to the lumbar region. About noon of the same day I found no effect from the calomel and castor-oil. An enema passed his bowels without producing a fæcal evacuation, and there was no change in the symptoms or improvement of the patient. I then called Dr. Wallace in consultation, who, upon examining the patient, coincided with my views and suggested that two drops of croton-oil be given. It was done and repeated in two hours, but without effect until late in the evening, when an enema, consisting of castor-oil, soap, salt, and warm water, produced one copious stool. No urine having passed, I managed to introduce a catheter, and, to my surprise, I succeeded in withdrawing one quart of urine, which proved to have a specific gravity of 1·024, and to contain no albumin, no casts, no blood-coloring matter, but to contain a normal quantity of urea, no sugar being present. No change of symptoms had taken place since morning, so I concluded to continue the treatment, and prescribed only thirty grains of bromide of potassium at bedtime. Early in the morning of March 30th Dr. Wallace and I met again and concluded to call in Dr. Gray for consultation.

The latter, after examining the patient, came to the conclusion that, provided we were able to exclude kidney disease, meningeal trouble, with a strong suspicion of syphilitic origin, would have to be considered next, and therefore he recommended the use of iodide of potassium, gr. viij, three times daily, bromide of potassium, 3 ss., three times a day, and hyoscyamine, gr. $\frac{1}{50}$, every four hours. From the time I introduced the catheter the day previous the patient did not urinate. I catheterized again at 4.15 P. M., March 30th, and withdrew a pint and a half of urine, which corresponded exactly with the urine of the day previous. The patient had been fed March 29th and 30th with gruel and beef-juice and water whenever he showed any inclination to take them. Thirst did not seem to trouble him. His general condition remained the same as upon the day previous; he would answer questions in a rather incoherent way. Upon being asked to get up and walk, he would do so without any apparent effort. At 6.15 of the same evening he was taken with a cough and expectorated a good deal of mucus. At 6.35 he became very restless, and his pulse ran up to 112. Five minutes later he had a convulsion. I administered at once some chloroform by inhalation, but without effect upon the convulsions. I telephoned at once to Dr. Wallace and Dr. Gray. The former was not at home. The latter responded to my call and recommended the use of amyl nitrite by inhalation, and, no effect being produced upon the convulsions, a hypodermic injection of thirty drops of tincture of veratrum viride. As already mentioned, the pulse was 112 five minutes before he had the convulsions; at 7.15 it was 140; at 7.25, 180, with a respiration of 28 a minute. The pulse varied between 180 and 160, with a respiration of 40, until 8.55, when I administered thirty drops of tincture of veratrum viride hypodermically. Three minutes afterward the pulse fell to 144. Five minutes later it was 140, and then it gradually fell until it came to 96, at 9.35, and remained so until the patient died, in convulsions, at 10.30 of the same evening. The following day Dr. Leuf performed the autopsy, and will relate to you the details of the same."

Report of the Autopsy, by Dr. Leuf.—"The patient was a strong, well-built male. The autopsy was held about twenty hours after death, and rigor mortis was well marked. Both kidneys was found in a state of the most intense congestion it was possible to see. The blood almost welled out of them as soon as the tension of their substance was relieved by section. Pressure caused additional free sanguineous exudation. They had a very deep purple color and were both alike. The bladder was empty. The other abdominal and the thoracic viscera presented nothing unusual in appearance as to congestion or other anomalous conditions. The pia mater was intensely injected and perfectly dry on the surface, while beneath it, upon the cerebral surface, there was a large amount of widely diffused extravasated blood. The hæmorrhage most likely originated in the smaller vessels of the pia at the bottom of the sulci, because when no blood appeared upon the surface it was found in abundance at the bottom of the fissures, and none was found on the surface of a convolution without its being discovered in the adjacent furrows in sufficient amount to distinctly separate the contiguous walls. In my opinion the meningeal inflammation was caused by the kidney congestion, but, as there is room for honest difference of opinion on this point, I prefer to leave its consideration to others."

Dr. William Wallace had been puzzled with the case. He had thought that there was no brain trouble, and had considered it renal. The condition of the brain surprised him. He considered the kidney trouble primary. He had never seen bloodier kidneys. He thought that Dr. Leuf's theory might be correct, but acknowledged that the results of the autopsy made him more puzzled than ever.

Dr. Stub was able to quote but one authority in favor of renal disease producing meningeal affections. A man in "von Ziemssen," in a long letter, held that kidney disease often produced meningeal trouble. Dr. S. G. Armor, he then recollected, had also made a similar statement at the Kings County Society. Acute hyperæmia resulting from nephritis might end in sudden death, but in this case it was more than a hyperæmia.

The President asked if Dr. Stub still considered the case one of uræmia.

Dr. Stub replied that he did not, and that he had made out the death certificate for lepto-meningitis.

Dr. Albert Brinkman remarked that Loomis said that renal disease often caused serous inflammations, and especially if an acute attack occurred during the chronic disease.

The President thought that the intense vomiting, without any other symptom, excluded uræmia. Inasmuch as much fluid would be evacuated by continuous emesis, it could not be expected that a normal amount of urine would be passed. The paralysis of the bladder was indicative of cerebral or spinal trouble. He thought the renal congestion accidental. We often found many internal congestions in case of sudden death. He thought there was hardly enough uræmia to account for the meningeal trouble. He would ask if there had been any other symptom besides vesical paralysis to indicate disease of the cord.

Dr. Stub answered, "No." In reply to the question, whether there had been anything noticed in the vomited material to indicate poisoning, Dr. Stub said that there had not.

Dr. Leuf explained that he believed the kidney trouble to have caused the meningeal inflammation for several reasons. The meningitis was in the first, or dry, or congestive stage, a condition rarely met with of so marked a type. The kidney congestion must have been of several days' duration, as the extensive and universal corpuscular infiltrations of the kidney substance demonstrated as seen by the microscope. Renal disease was not infrequently the cause of not only cardiac, but also cerebral and meningeal disorders; and, while it was easy to explain this on the supposition that the increase of arterial tension all over the body, resulting from renal affections, caused secondary congestions and inflammations in remoter organs, the vascular apparatus of which was weakest, the reverse could not be rationally inferred. It had just appeared that only three authoritative statements could be adduced to uphold the views he had just expressed. There certainly were many more, and he knew of none just now that upheld the contrary view, that meningitis was ever the cause of nephritis. It also seemed to him that the urine that had been drawn off by catheterization had been in the bladder for some time. The catheter was not passed at first, because percussion over the hypogastrium elicited a tympanitic sound, but then a partly filled bladder did not project up into the abdomen and was usually covered by coils of the ileum distended more or less with gas. The president had thought fit to assume a very recent origin of the nephritis, because of the lack of uræmic symptoms, and accounted for the small amount of urine voided by the copious discharge of liquid in continuous emesis. Now, it seemed just as plausible to suppose that in spite of urinary retention, due to intense nephritis, sufficient urea was passed by the mouth in the vomited matter to prevent uræmic symptoms. Concerning the chair's allusion to the congestions so common in cases of sudden death, he would only say that, having made a very large number of autopsies in just such a class of cases, he had not only never seen anything like such a congestion in such cases, but even not in *any* kind of case whatever.

Dr. Stub asked if the coagulability of the blood was not a sign of ante-mortem extravasation, and its non-coagulability of post-mortem effusion.

The PRESIDENT replied that it was not a safe rule to follow, as some poisons might prevent coagulation.

Dr. STUB wished to know of what kind of poisoning the case under discussion could have been.

Dr. SEWUNY suggested poisoning with arsenic.

Dr. STUB rejoined that that could not be, because there was no gastro-intestinal disturbance visible at the autopsy, no purging during life, and no reason to suspect it in any way.

Dr. ECCLES asked if it might not have been poisoning with iodide of potassium.

Dr. STUB thought it might more likely have been with chlorate of potassium.

Dr. W. H. FARRINGTON wished to know if there had been any evidence of blood in the urine drawn during the patient's illness.

Dr. STUB replied that there had not.

Dr. LEUF alluded to a case of poisoning with chlorate of potassium, in which he had made an autopsy for the coroner. It was that of a girl about fifteen years of age, and her mother had given her by mistake about eight drachms of this drug in as many hours. The kidneys in that case were almost exactly like those he had described this evening, except that the Malpighian corpuscles appeared as *black* punctate bodies, and so did all the solitary follicles of the intestines.

Dr. SULLIVAN was not satisfied with the diagnosis. He thought the conditions of the kidneys and brain were caused by the convulsions. He had had a similar case some time before—that of a man who came home, ate his dinner, became unconscious (apparently apoplectic), regained consciousness later in the evening, rambled in his conversation, was almost well next morning, and wholly so in a few days. This man did not know whether he had had convulsions or not, although such was stated to have been the case. He was a chronic dyspeptic. The whole trouble was probably due to some disturbing article of food. The speaker believed the case under discussion to have been similar to his, and death to have been due to exhaustion of the nervous system. Sudden cold might have caused the attack. He was still not satisfied as to the cause of death and would like to be enlightened.

Dr. STUB replied that the last speaker's remarks would have been more to the point if the case under discussion had begun with convulsions. He would like Dr. Leuf to answer the question as to the cause of death, because he ought to know it best.

Dr. LEUF informed Dr. Sullivan that it was acute leptomeningitis.

The PRESIDENT did not believe that the arterial tension caused by renal congestion could be sufficient to cause a meningeal hæmorrhage.

Dr. FARRINGTON recalled a statement of Dr. Stub's about Dr. Gray's having suspected syphilis, and desired to know if any evidence of it had appeared.

Dr. STUB replied that there had not, and that Dr. Gray was himself satisfied of it.

Malignant Tumor of the Sacrum.—Dr. LEUF presented the specimen with the following abstract from the notes of the last attending physician: On October 11, 1883, the diagnosis was compression of the spinal cord, but was only inferential. Eight days later, upon consultation with Dr. John C. Shaw, a small tumor of the sacrum was noticed to the right of the median line. On January 10, 1884, the diagnosis was changed to sacral caries, but with a doubt as to its correctness. From May 9, 1884, the diagnosis of sacral tumor was positively adhered to until the day of death, January 6, 1885. Neither lower limb was wholly paralyzed. Slight motion was always possible. There was marked œdema below the knees, and later all below the hips was very much swollen. Acetate of potassium was given to relieve the dropsy. A large bed-sore formed at the site of the tumor and in the vicinity. There were always marked pain and insomnia unless morphine injections were given. Fainting spells were frequent. The temperature ranged from 101° to 102° F., and some tenths of a degree above; the pulse from 96 to 120 a minute. Occasionally there were hæmorrhages from the ulcerated tumor. Microscopical examination of some of the tumor obtained with a hypodermic syringe caused a diagnosis of encephaloid sarcoma to be made, based upon the presence of a profusion of round cells with very little stroma. The mode of death was by syncope. From puberty the patient had always been a poor eater. He never liked good substantial food, such as meat and vegetables, but only pies, cakes, and sweets. He had always been below par in appearance, looking thin, pale, and delicate. Several years before the beginning of the disease he had a fall upon the sacrum, causing severe local pains for several days, but from this he apparently fully recovered.

The speaker had been requested to make the post-mortem examination, and the following was an outline of what was found. All the thoracic abdominal viscera presented the usual appearances noticed in those who died of inanition. They were all pale and atrophied, and the intestines contracted to their utmost. A tumor was found projecting forward and upward from the anterior surface of the sacrum so as to fully half fill the pelvic cavity. Upon pressure it yielded a slightly crepitant sensation like the yielding of a very fine and incomplete calcareous shell, a sensation quite common in osteo-sarcomatous growths, on account of the distension and thinning of the bone by the contained growth. There was no discoloration of the coverings of the intra-pelvic portion of the tumor. Posteriorly, there was a gangrenous opening about 2 ctm. in diameter on a line crossing the two posterior-superior iliac spines, and a little to the right of the mesial plane. It was located on the summit of a lump projecting about 4 ctm. The skin of the whole posterior pelvic region was destroyed and the bone laid bare by a deep and extensive bed-sore, involving to some extent the exposed bones. The odor was very characteristic of malignant tumor. The growth had extended laterally so as to involve the auricular surfaces of both ossa innominata, and the muscles in contact with them in the immediate vicinity of the sacro-sciatic foramina. The pyriformes were wholly changed to the appearance of the growth itself, except that they were a little softer. The outlines of the muscles involved were also so blended that they could hardly be discerned. The sacrum, the lower two lumbar vertebræ, the coccyx, and the posterior thirds of the innominata were removed, and, on section being made through the growth, it appeared in spherical sections united by a connective tissue, gelatinous and fluid substance.

Both lower limbs were enormously distended with œdema, from the center of the thigh down. They appeared much as if affected with elephantiasis. Otherwise the body was as extremely emaciated as it could possibly be. Additional bed-sores were found along the spines of the scapulæ, extending at least 2 ctm. above and below, and exposing the aponeurosis and substance of the trapezius and deltoid. There were some even on the back of the elbows. Every spinous process, from that of the vertebra prominens to the large sore at the site of the tumor, had button-holed its way through the skin, forming a series of irregular circular openings all along the spinal column.

Dr. ECCLES said the patient had been in his hands for four months. Two consultations had been held with Dr. Shaw, and for some weeks Dr. Benjamin Westbrook had attended with him. When he was first called the patient complained of intense pain in the lumbar region combined with sciatica. The character of the lumbar pain suggested a rheumatic complication. Treat-

ment with large doses of salicylate of cinchonidine speedily relieved this, leaving the neuralgia as intense as ever. After this treatment he no longer endured such excruciating pain when in a recumbent position. Up to this time no one had thought of his trouble having any mechanical cause. It was looked upon as a simple neuralgia. Later on, however, the symptoms began to appear in the other leg, suggesting some common cause in the abdominal region. A condition of hyperæsthesia of the feet and lower part of the legs began to trouble him. He could not endure the lightest touch. The liniments applied hurt him when first put on. Sometimes he complained of prickling pains in the soles of the feet as if needles were being inserted. After this œdema set in, beginning with the toes and working up both limbs in a slowly progressive manner to a considerable distance above the knees. The urine was carefully watched from time to time for kidney trouble, but none was found. Constipation was a constant symptom, and required continual attention. As the trouble progressed the young man became less and less able to move around, even with the aid of his crutches, and was at last permanently confined to his reclining chair. To give him some rest and change, Dr. Westbrook devised an adjustable cot upon which he could be placed occasionally. From quite an early date in his trouble the temperature kept above 101°, sometimes running as high as 103°. This suggested to Dr. Shaw tuberculosis as a complication, but the post mortem did not confirm it. Before the speaker had called in Dr. Westbrook two homœopathic practitioners had been invited to see the patient without his knowledge. Their diagnosis, as afterward discovered, was aneurysm of one of the iliacs. They first heard the distinct *bruit* which then appeared but afterward passed away. The patient survived by several months the time they set for his death. Up to and beyond this time every attempt at discovering an enlargement by pressure through the abdominal wall failed. A slight enlargement, however, did appear over the right sacro-iliac synchondrosis looking more at first like an œdematous spot than anything else. This gradually grew larger, spreading toward the sacrum. From the time when the symptoms first appeared bilaterally until the tumor became too large for its presence to be doubted, his diagnosis had hung between disease of the sacro-iliac joint and sarcoma. Dr. Benjamin Westbrook first demonstrated the presence of the tumor by touching it through the rectum. The aneurysm theory of the homœopathists was rejected by all the regular physicians who saw the patient. Dr. Wight, some two months after Dr. Westbrook's examination, pronounced it osteo-sarcoma. The case was a remarkable one in every way. It was treated by all sorts of practitioners during some part of its career. Even the spiritualists had a trial of their skill. The patient was an unusually bright young man, a student of Columbia School of Mines, and had just returned home from an extended tour in Egypt, Palestine, and Central Europe, when he was attacked. He took the Oriental trip because of ill-health.

Dr. Stub had not seen the case under discussion, but had met with a similar one. A man had a slight sciatica; afterward both legs were affected; for a period of several weeks he steadily persisted in efforts to walk in this condition. Then he had to go to bed; he could hardly shift his position in bed without suffering excruciating pain; there was fever with loss of appetite; he could not get up even with the aid of machines; the pain only existed in the lower limbs. Dr. A. Jacobi came over from New York and diagnosticated myelitis. The patient was blistered and counter-irritated in various ways, and received all kinds of medication. The diagnosis was adhered to, until a movable tumor of the sacrum was discovered and a diagnosis of cancer made. Subsequently there occurred what was believed to be a general cancerous nodular infiltration.

Dr. Eccles stated that a diagnosis of myelitis had also been made by the attending physician in the case reported by Dr. Leuf, and adhered to almost to the last, although the physician was acquainted with the diagnosis of sacral tumor made by the preceding attendants. We sometimes saw strange coincidences. While he was in Europe the preceding summer, in Kilmaurs, Ayreshire, Scotland, he met with the case of a young man of about the same age as the patient whose case had been reported, and with almost exactly the same history, who died at almost the same time. There was no autopsy in that case.

The President said that there were two or three clinical points in the case to which he would like to call attention. The arterial *bruit* which had misled the so-called homœopathic physicians was synchronous with the radial pulse, of about the same character as the sound produced in an artery of medium size by pressing upon it with the stethoscope, and audible over the vertebral column from the upper dorsal to the upper sacral region. He was unable to give any explanation of it, but thought that no experienced auscultator should have mistaken it for an aneurysmal *bruit*. The second fact of interest to the clinician was the elevation of temperature which prevailed throughout the time that he had had the patient under observation. It suggested the idea of vertebral caries, and the diagnosis, so far as he was concerned, had lain between caries and a malignant tumor. After several aspirations of the swelling, which occupied the sacral region, between the posterior spinous processes of the ilia, more marked upon the right side, it was pretty certain that there was no pus, for nothing but blood ever appeared in the hypodermic syringe. At that time he was not aware that sarcomatous growths gave rise to pyrexia, but he had since seen an account of some observations by a European physician, whose name had escaped his memory, which went to show that this did occur. Palpation of the tumor through the rectum had not been very satisfactory, as it could barely be reached with the finger, and was too distant to be accurately mapped out. He remembered a similar case in which he had made an autopsy for Dr. McCorkle and Dr. Barker, in which also the growth had made its way through the greater sacro-sciatic foramen. In that case there had been a sciatic neuritis, presumably excited by the irritation from the pressure of the growth, and the perineurium was thickened to such an extent as to enlarge the nerve to at least twice its ordinary dimensions.

He had been informed by a credible person that, toward the last, the unfortunate boy had been put under the care of a female whose method of treatment was to occupy the same bed with the patient and impart to him some of her "vitality," "animal magnetism," or whatever she called it. This was, to him, a new system of practice.

Dr. Stub remarked that there had been an elevation of temperature in his case.

The President thought that it might have been due to the erosion of bone.

Dr. Eccles: "Isn't the age unusual?"

Dr. Leuf: "For carcinoma it is, but for sarcoma it is not."

An Incompatible of Antipyrine.—Dr. Eccles announced that some days previous, while making pharmaceutical investigations, he had had occasion to mix some sweet spirits of niter with a solution of antipyrine. At first the mixture was clear and colorless, but, after some hours' standing, became green. The optical appearances of this fluid were identical with those of the anilines, and, as antipyrine was a coal-tar product, he supposed the change was due to the formation of a green aniline, and so it had proved to be. This incompatibility was all the more important as both substances were used for antipyretic purposes, and might be prescribed together.

Miscellany.

The International Medical Congress.—In an editorial article entitled "A Medical Star Chamber," the "Boston Medical and Surgical Journal" says:

"The Executive Committee of the committee appointed to arrange for the meeting of the International Medical Congress in America in 1887 has recently held a meeting in New York city. An editorial in the 'Journal of the American Medical Association' contains all the information concerning it that is made public. The little that is vouchsafed us has certainly the merit of exciting curiosity as to what has been left untold. To prevent all further misunderstanding, both at home and abroad, the committee unanimously adopted the following declaration of independence: 'That the actions of this Executive Committee are final, not being subject to revision, amendment, or alteration, by either the Committee of Arrangements or the American Medical Association.' How will the Committee of Arrangements and the American Medical Association like that? The opinion of Mr. Randall, delivered no longer ago than last May, was urged in support of interference with the original committee for alleged too great independence of action. If of force at that time it is equally good authority at present· 'I might add, in addition,' said Mr. Randall, 'that the theory that a select committee created by a body with certain defined powers and duties gives any *vested rights*—so to speak—which places it above or beyond the power of the creating body to review or regulate, is one not only without precedent in parliamentary law, practice, or history, but is untenable on any ground of parliamentary principle.' Prof. Frederic S. Dennis was appointed Associate Secretary-General, and *another* was appointed Chairman of the Finance Committee. Why *another's* name should be concealed from an anxious public we can only conjecture. Is the anonymous gentleman too modest to allow his name to appear? Is some nameless individual to assume the expenses of the Congress? Is secrecy necessary as a safeguard against theft, or is the committee ashamed of its appointment? It must be a very bad choice indeed which can be worse than such ostentatious secrecy. It would seem as though this branch of the enlarged committee was bound to destroy what little respect was left for the proposed International Congress."

The same journal publishes the following letter from Dr. Henry I. Bowditch:

"Boston, *October 8, 1885.*

"Mr. Editor: Since Dr. J. S. Billings, as general secretary of the committee for arranging the International Congress for 1887, informed me that I was selected as one of the vice-presidents of the Congress, I have had no *official* notice either of my summary displacement by the new committee at its meeting in Chicago (June 24th) or of my reinstatement by the same committee (September 3d). For this and other reasons to be named, I ask a place in your journal for the following statement: When urged by some friends to sign the protest made in several cities by gentlemen opposed to the action taken at New Orleans, I replied, 'It would be absurd for me to do so, because the committee has already expelled me from office.'

"Since that time I have watched with interest the course pursued by the 'Journal of the American Medical Association,' and also that of the new committee for the International Congress. I have read with pain the perpetually recurring bitterness and insinuations against all those who had dared to express opinions adverse to the doings of the association, or those of its new committee. I was surprised and disgusted while reading the editorials of August 1st, entitled 'The International Medical Congress and its Enemies,' and that of August 29th, 'International Medical Congress of 1887 and the American Medical Association.' From these editorials any foreigner reading them would not have the least suspicion that the controversy on the 'code' had any share in the imbroglio at present existing. I wholly deny that those who now disapprove of the course the association and its committee have taken are the 'enemies of the International Congress.' On the contrary, they are, in my opinion, its best friends.

"Notwithstanding my objection to such editorials, I have continued to decline to sign the protest in the hope that, by so acting, I might perchance do something toward the promotion of professional harmony in America.

"But the last manifesto of the committee and gross assumption of despotic power for making all future arrangements for the Congress (*vide* 'Executive Committee of the Ninth International Congress,' 'Journal of the American Medical Association,' September 3d) convince me that I can remain no longer in the position in which the new committee (as I learn from the journals) placed me without my knowledge or consent at their meeting in September.

"That manifesto by the new committee is equaled by nothing in the history of medicine in this country, save the arrogant position taken by the Judicial Council of the American Association at its meeting in Cleveland in 1883. The Council, through its chairman, declared that the Council 'took the responsibility' of requiring every member to sign *annually* the code of ethics, or to lose his right to meet his fellows at the gatherings of their association for the advancement of the sacred cause of Medical Learning!

"That decision of the Council was disgraceful alike to the Council as declaring its assumption of power which it did not legally possess, and to the association for its pusillanimity in submitting, *even to the present day*, to the insult then inflicted upon it—a so-called scientific and learned body.

"To one who looks behind the scenes and knows whose intellectual power, combined with honest but misguided bigotry, has influenced the Council of the American Association, there is no difficulty in understanding the present position of the 'Committee for the International Congress.'

"The same dominant mind governs both. I loathe all such ungenerous and bigoted work, and therefore retire from office in the same public manner that I have been placed there. In declining thus publicly the honor it would confer on me, I am only imitating the example set by the committee in its intercourse with me.

"Respectfully yours,

"Henry I. Bowditch, M. D.

"P. S. By a singular *coincidence* I have received to-day, since the above was in type, from the chairman and secretary of the committee, official notice of my appointment to the office of vice-president of the International Congress. Upon mature reflection I can not alter my decision as above given."

The "Medical News," of Philadelphia, announces the declinations of Dr. Henry F. Campbell, of Augusta, Ga.; Dr. E. O. Shakespeare, of Philadelphia; Dr. Henry G. Beyer, of the navy; Dr. John J. Mason, of Newport, R. I.; Dr. Jerome H. Kidder, of Washington; and Dr. J. M. Flint, of the navy.

Editorially, the "News" says:

"In the beginning of the Congress controversy extreme solicitude was expressed by some members of the association for the assertion of its supreme authority in everything pertaining to the organization of the Washington meeting, and its journal devoted many pages to advocating this point. Now, however, that the new Executive Committee has proclaimed its independence of the parent committee and of the association, by formally declaring that its acts are 'not subject to revision, amendment, or alteration by either the committee of arrangements or the American Medical Association,' the journal has not a word to say against their usurpation of power, or about the propriety now of maintaining the authority of the association in the premises. It does not point out how the *new* committee have laid themselves open to 'the charge of having ignored the body from which its existence and all its powers had been derived,' or how *they* 'coolly turn the association into a "foot-ball" and contemptuously kick it out of their way.' It no longer talks about members making 'a bold attempt to use the national character and prestige of the American Medical Association as a "decoy duck" to obtain their own appointment to office.' The authority of the association is openly defied by its own committee, and its journal suddenly becomes silent on the subject."

The "Pacific Medical and Surgical Journal," of San Francisco, closes an editorial article as follows:

"The American committee had one chance to retrieve itself, but that is past, for it has ignored the representations of the profession, both in Europe and our own country. Now we shall have no compro-

mise. Those blatant notoriety hunters, with the impudence which has characterized them from the very commencement of their action at New Orleans, have endeavored to carry out their plans in defiance of the wishes of the professional world, and to the disgrace of their own country. They have shown themselves to be utterly regardless of everything but vainglory. Through a premeditated and carefully arranged plan, suddenly sprung upon the association, they jumped into a position of power, and that power they have abused until their very names are becoming execrable in the ears of their countrymen. The profession must either indorse the action of Dr. Billings's committee, or request that the Congress be held in some other country, and we advise our brothers to withhold all subscriptions until one or other of these conclusions has been adopted. In the event of no action being taken in the matter, then let those men play at having a congress, and handle their puppets like any other showmen; but never let the American nation forget itself so far as to countenance such mimicry as a national event."

Regulations for the Maintenance of Quarantine Inspections on the Northern Frontier of the United States.—The following circular, dated October 10th, has been issued by Surgeon-General Hamilton:

To the Medical Officers of the Marine-Hospital Service, Customs Officers, and others concerned:

The act approved April 29, 1878, entitled "An Act to prevent the introduction of contagious or infectious diseases into the United States," provides that no vessel or vehicle coming from any foreign port or country where any contagious or infectious disease exists, or any vessel or vehicle conveying persons, merchandise, or animals affected with any contagious disease, shall enter any port of the United States, or pass the boundary-line between the United States and any foreign country, except in such manner as may be prescribed under said act.

Attention is now directed to the prevalence of the contagious and infectious disease of small-pox in Montreal and other places in the Dominion of Canada, and the law referred to is held to apply alike to trains of cars and other vehicles crossing the border and to vessels entering ports on the northern frontier.

Because, therefore, of the danger which attaches to the transportation of persons and baggage, and articles of merchandise, or animals, from the infected districts, the following regulations are framed, under the direction of the Secretary of the Treasury, and subject to the approval of the President, for the protection of the health of the people of the United States against the danger referred to:

1. Until further orders, all vessels arriving from ports in Canada, and trains of cars and other vehicles crossing the border-line, must be examined by a medical inspector of the Marine-Hospital Service before they will be allowed to enter the United States, unless provision shall have been made by State or municipal quarantine laws and regulations for such examination.

2. All persons arriving from Canada by rail or otherwise must be examined by such medical inspector before they will be allowed to enter the United States, unless provision has been made for such examination as aforesaid.

3. All persons coming from infected districts, not giving satisfactory evidence of protection against small-pox, will be prohibited from proceeding into the United States until after such period as the medical inspector, the local quarantine, or other sanitary officer duly authorized, may direct.

4. The inspectors will vaccinate all unprotected persons who desire, or are willing to submit to, vaccination free of charge. Any such person refusing to be vaccinated shall be prevented from entering the United States.

5. All baggage, clothing, and other effects, and articles of merchandise, coming from infected districts, and liable to carry infection, or suspected of being infected, will be subjected to thorough disinfection.

6. All persons showing evidence of having had small-pox or varioloid, or who exhibit a well-defined mark of recent vaccination, may be considered protected, but the wearing-apparel and baggage of such protected persons who may come from infected districts, or have been exposed to infection, will be subjected to thorough disinfection as above provided.

7. Customs officers and United States medical inspectors will consult and act in conjunction with authorized State and local health authorities so far as may be practicable, and unnecessary detention of trains or other vehicles, persons, animals, baggage, or merchandise, will be avoided so far as may be consistent with the prevention of the introduction of diseases dangerous to the public health into the United States.

8. Inspectors will make full weekly reports of services performed under this regulation.

9. As provided in Section 5 of said act, all quarantine officers or agents acting under any State or municipal system, upon the application of the respective State or municipal authorities, are empowered to enforce the provisions of these regulations, and are hereby authorized to prevent the entrance into the United States of any vessel or vehicle, person, merchandise, or animals prohibited under the act aforesaid.

10. In the enforcement of these regulations there shall be no interference with any quarantine laws or regulations existing under or to be provided for by any State or municipal authority.

The Transportation of Dead Bodies.—At a recent meeting of the Michigan State Board of Health the secretary reported that, by invitation, he had attended, September 16th, in Lansing, a meeting of the Michigan Association of General Baggage Agents, and taken part in the discussion of the subject of the meeting, "The Transportation of Dead Bodies." At that meeting a committee was appointed to draft rules for the guidance of agents of railroad companies in the transportation of dead bodies. The chairman of that committee, Mr. H. P. Dearing, the general baggage agent of the Michigan Central Railroad, appeared before the board and presented the rules as adopted by the committee. He said the design was to make a set of rules that would meet the views of the several State boards of health, and be adopted by all the great lines of railroad in the United States, so that there should be uniformity of practice, thus better protecting the lives of railroad employees and those of travelers. Rule 1 absolutely prohibits the transportation of bodies dead from small-pox, Asiatic cholera, typhus fever, and yellow fever. Rule 2 provides that all other dead bodies may be transported, provided they are incased in an antiseptic interment sack, hermetically sealed, in addition to being in a coffin, and this in a tight wooden box, except those dead of diphtheria, scarlet fever, typhoid fever, erysipelas, measles, or other contagious and infectious diseases, which must be wrapped in a sheet thoroughly saturated with a strong solution of chloride of zinc (one half pound of the chloride of zinc to a gallon of water) before being incased in the hermetically-sealed sack. The coffin must be surrounded by sawdust saturated with a solution of chloride of zinc of the same strength. Rule 3 specifies that no person or article that has been exposed to the infection may accompany the body. Rule 4 provides that some one must accompany the body; and forms for certificates are given. After discussion of the subject, the board approved of the rules.

The American Academy of Medicine.—At the ninth annual meeting, to be held at the New York Academy of Medicine, on Wednesday and Thursday of next week, papers are expected to be read as follows: "The Study of Medicine as a Means of Education," by Dr. Robert Lowry Sibbet, of Carlisle, Pa.; "Medical Supervision in Student Life," by Dr. Charles McIntire, of Easton, Pa.; "Western North Carolina as a Health Resort," by Dr. Henry O. Marcy, of Boston; "The Importance of Climatology considered as a Regular Branch of Study in Medical Colleges," by Dr. E. H. M. Sell, of New York; the president's address, entitled "What is Medicine?" by Dr. Albert L. Gihon, of the navy; "Medical Evidence," by Dr. Thomas J. Turner, of the navy; "Report on Laws regulating the Practice of Medicine in the United States and Canada," by Dr. Richard J. Dunglison, of Philadelphia, and Dr. Henry O. Marcy, of Boston; "Health Officers, Ancient and Modern," by Dr. Benjamin Lee, of Philadelphia; "Micro-organisms and their Relation to Disease," by Dr. Samuel N. Nelson, of Cambridge, Mass.: "Observations on the Relation of Bacteria to certain Puerperal Inflammations," by Dr. Ernest W. Cushing, of Boston; "Medical Licenses and Medical Honors," by Dr. Edward Jackson, of Philadelphia; "The Physician and his Patient," by Dr. John Devin Kelly, of Utica, N.Y.; "Physicians of Delaware in the Eighteenth Century," by Dr. Lewis P. Bush, of Wilmington, Del.

Georgetown University.—The Washington correspondent of the Philadelphia "Medical News" says that, at the time that Surgeon-General Hamilton, of the Marine-Hospital Service, handed his resignation to the President, he also resigned the professorship of surgery in the Medical Department of Georgetown University. It was accepted with reluctance, and ex-Surgeon-General Wales, of the navy, was finally appointed to the vacancy. When, however, it was learned that the President would not accept Dr. Hamilton's resignation, Dr. Wales at once resigned the professorship, whereupon Dr. Hamilton was re-elected to the chair.

Diphtheria of the Œsophagus.—Dr. H. D. Fry, of Washington ("Am. Jour. of the Med. Sci."), contributes an interesting study of this rare affection, and reports a case which occurred in his own practice. The diagnosis of diphtheria of the œsophagus is extremely difficult. In most cases it is absolutely impossible to recognize the disease. This difficulty is met with not only when the œsophageal mucous membrane is primarily the seat of diphtheritic inflammation, but also when it is implicated by extension of the false membrane from the pharynx or larynx. In the vast majority of the reported cases its presence was not suspected until revealed by post-mortem examination. Symptoms, at most, only warrant a suspicion of the existence of the affection. An important indication is the expulsion, by the mouth, of bands of false membrane, provided no symptoms exist to indicate that the air-passages are involved. The expectoration of a membranous cast of the œsophagus is the only positive sign of the disease. The obscurity which accompanies nearly all affections of the œsophagus is well illustrated by the experience of Steffen. Out of forty-four cases, including diphtheria, hyperæmia, catarrhal inflammation, ulceration, ecchymosis, and gangrene, the diagnosis was made in only three; the remainder were found on post-mortem examination. Dr. Fry concludes his paper with a careful analysis of the symptoms which were observed in the twelve cases which he has been able to find fully reported in literature.

The Limitations of Colotomy in Disease of the Rectum.—Dr. Charles B. Kelsey, of New York (*Ibid.*), defines the following as the indications for colotomy: 1. In congenital malformations of rectum or anus in children in which a tentative operation in the perinæum has failed to reach the rectal pouch. 2. In intestino-vesical fistulæ. 3. In tumors occluding the rectum which can not be relieved by any other means—dilatation, division, hot water, or electrolysis. 4. In non-cancerous, simple, or specific stricture and ulceration of the rectum (with or without fistulæ), where the disease can not be relieved by proctotomy or dilatation, or division of the fistulæ and local treatment of the ulceration. 5. In cancer where the disease can neither be removed nor the passage re-established, and where death is probable from obstruction—except in cases where the immediate dangers of the operation more than counterbalance any good likely to be gained by it. 6. In volvulus or intussusception of the colon or sigmoid flexure, where reduction by the aid of laparotomy has been found impossible.

The Choice of Methods in Abdominal Delivery.—Gastro-hysterotomy has been improved by the introduction of the uterine suture, and lives have been saved that must otherwise have been lost; but no change in the old operation can compensate for the delay and intermeddling so generally indulged in (where the knife is the only remedy that promises success), to the fatal termination of the case. In an instructive article, Dr. R. P. Harris, of Philadelphia (*Ibid.*), shows that it is in vain to practice this operation in the United States unless it is done in good season. Since January 1, 1875, 29 out of 38 cases have ended fatally, and 21 children were extracted dead, leaving 17, of whom 4 soon perished from causes occurring before delivery. Twenty-eight women were in labor from one day to two weeks, and fifteen of them more than three days. The Sänger modification with its simplifications has been performed 12 times, saving 6 women and 10 children, of which 5 cases belong to the credit of Dr. Leopold, of Dresden, who saved 4 women and 5 children. Of 8 German cases, 6 ended in recovery. These women were in labor respectively 12 hours, 8, 30, "some hours," and 16 hours, and in 1 case the time was not mentioned. The women whose cases were marked "favorable" by reason of their condition before the operation all recovered. A tabular record of cases is given by Dr. Harris.

Laparo-elytrotomy also numbers 12 cases, with 6 recoveries and 7 children saved. Nine of the cases belong to New York city and Brooklyn, where 6 women and 5 children were saved. These 6 women were in labor respectively 11 hours, 4 days, 16 hours, a week, 8 hours, and 22 hours. There were 4 "*favorable*" cases among the 12, all of which ended in recovery. These two cities have a credit of 11 Cæsarean operations, saving but 2 women and 2 children. In 10, the prognosis was "*unfavorable*." In cases made more serious by delay, laparo-elytrotomy promises better than gastro-hysterotomy, and should be preferred to it. It also promises more favorably for British cases, so far as we can judge by New York, where the mortality was formerly equal to that of England. A table of the operation is given.

The Porro-Cæsarean operation, Dr. Harris shows, is *par excellence* the method for hospitals, where the women should be under anticipative treatment and operated upon very early in, or just prior to, labor. The Müller modification is preferable where the placenta is upon the anterior uterine wall, or the fœtus dead and putrid. Dwarf subjects require that the delivery under the knife should be effected very early, as exhaustion occurs after a short effort of nature, and death is apt to result in such cases. The Porro operation has been the most successful in the cases of dwarfs.

The Causal Relation of Obstructed Cardiac Circulation to Lymph Stasis.—In a learned article, Dr. S. C. Busey, of Washington (*Ibid.*), points out that retardation, or arrest of the current of the fluid in the thoracic duct at or near its outlet into the subclavian vein, may produce dilatation, distension, and rupture of lymphatic vessels, and consequent effusion of chyle and lymph into the serous cavities. The remoteness of the effects from the obstacle interrupting the current of the fluid may depend upon various concomitant conditions, especially upon the anatomical integrity and the distensibility of the vascular walls. When the impediment to the flow of chyle and lymph occurs at or near its outlet, the area of stasis and ectasis will necessarily depend upon the duration and extent of such obstacle; and hence, when the area of ectasia is extensive, the manifest inference is that the cause has been one of gradual development and protracted duration. The influence of partial obliteration or stenosis of the thoracic duct at or near its termination in the causation of dilatation or rupture of some part of the lymph-vascular system can not be doubted. The evidences of experimentation must be accepted as conclusive. The effects of stenosis produced by the gradual encroachment from disease of the duct or of surrounding and contiguous tissues and structures are shown by clinical and post-mortem citations. In this latter class of cases the ectasia is gradual in its development and more extensive in its field. In cases where the lymphangiectasis was consequent upon the slowing or interruption of the venous blood-current in the left subclavian vein, the relation of cause and effect seems equally well established. Dr. Busey shows that such diseases of the heart as slow, impede, or stagnate the venous blood-current in the left subclavian or innominate vein may also produce lymph-stasis.

The Predisposing Causes of Aneurysm.—In a valuable paper Surgeon-General Hamilton (*Ibid.*) presents an elaborate study of the predisposing causes of aneurysm. So far as his inquiry has extended, the only constant element among all the alleged causes of aneurysm is that of climate. Neither syphilis, nor alcoholism, nor occupation, nor heat, alone, appears to have an appreciable influence on the causation of this disease. As to how far the influence of diet may extend in the production of aneurysm he has been unable to form any conclusion, but it is possible certain kinds of food may have a powerful influence.

The Academy of Medicine's Section in Practice of Medicine held a regular meeting on Tuesday evening, the 20th inst., at which Dr. Laurence Johnson read a paper on "The Choice of Remedies," and a general discussion took place on the question, "Is Typhoid Fever ever of Spontaneous Origin?" We would suggest that a somewhat closer approach to accuracy in the cards of announcement would not be amiss. On the card announcing that meeting Dr. Laurence Johnson figures as Dr. Lawrence Johnson, Dr. W. H. Thomson as Dr. W. H. Thompson, Dr. J. Haven Emerson as Dr. F. Haven Emerson, and Dr. S. Oakley Van der Poel as Dr. J. Oakey Vanderpoel.

The Brooklyn Pathological Society.—Dr. Daniel Ayres will deliver his second lecture on "The Pathology of the Inflammatory Process" at the next meeting of the society, to be held at the Brooklyn Eye and Ear Hospital on Thursday evening, the 29th inst.

The New York Academy of Medicine.—At the meeting of the Academy held on Thursday, the 15th inst., Dr. F. A. Castle, the treasurer of the Board of Trustees, reported the final payment of two thousand dollars on the mortgage on the Academy's property. This leaves the Academy entirely free from debt.

THERAPEUTICAL NOTES.

The Use of Iodoform Collodion, especially in Neuralgia.—Dr. William Browning, of Brooklyn ("Am. Jour. of the Med. Sci.") gives his experience with this remedy for external application, together with notes on the preparation itself, and a brief study of its action. The strength usually employed is one part of iodoform to fifteen of collodion. Half an ounce is usually sufficient for a single application. Dr. Browning has found it most effective when painted on in very thick layers, which may be conveniently done with the usual camel's-hair brush. As soon as one coating becomes a little firm another is applied, and so on until it appears to have an average thickness of $\frac{1}{2}$ mm. In the neuralgic cases a cure, when effected, was usually accomplished with one or two applications. The troubles found most amenable to this treatment were narrowly localized neuralgias, especially when corresponding to some particular nerve and not dependent on any demonstrable lesion. In fact, if a neuralgia, or what is thought to be one, proves intractable to this means, we should doubt its being a purely functional affection, and look carefully for some tangible cause. It has thus a certain diagnostic, as well as a therapeutic, value. Several times its complete or partial failure has led to a more searching and successful examination. Even in such cases much temporary relief is often afforded. Supra-orbital neuralgias, even of malarial origin, particularly if the miasmatic infection dates back some time, seem quite amenable to this treatment. It is not recommended as a substitute for the use of quinine, but only as an adjuvant where the latter fails or acts too slowly.

The Use of Strychnine in Nervous Disease.—Dr. Landon Carter Gray, of Brooklyn (*Ibid.*), reports five cases which show that strychnine was not well borne in two cases of severe acute myelitis, or in two cases of subacute poliomyelitis; that doses of $\frac{1}{25}$ of a grain, continued for four days, three months after the onset of transverse myelitis with early extension to the lateral columns, suddenly induced alarming symptoms of poisoning; that one patient with chronic general myelitis of traumatic origin was greatly benefited, as was likewise one with general myelitis in which the onset had been gradual; that in five cases of progressive muscular atrophy it acted remarkably as a stimulant; and that, as Dr. Weir Mitchell has indicated, it was decidedly beneficial to persons with neurasthenia who, after eight or ten weeks' treatment with rest and forced feeding, were taken out of bed, although it failed to agree with three subjects of the same affection treated in the ordinary way.

The Treatment of Extra-uterine Pregnancy with Electricity.—Dr. Henry G. Landis (*Ibid.*) remarks that it may be regarded as proved that electricity in some form is a specific cure for extra-uterine pregnancy. It arrests the growth and destroys the vitality of the embryo and cyst, and its use is followed by a truly remarkable disappearance of all or the greater part of the growth in a short time. This at least is true when the electricity is used during the first half of the pregnancy. As we approach the period of viability in the child the risk of rupture of the cyst diminishes, and the propriety of surgical interference at or near term becomes greater. The great advantage of the faradaic current over all other forms of electricity has been shown, but opinion is not yet settled as to whether we should use a local current for a long time or a strong current briefly, and how many repetitions of the application are necessary. To determine these points, Dr. Landis has conducted a series of experiments based upon the supposition that success is achieved by the death of the embryo, the *specific* value of the method being that the fœtus will surely be killed if it gets a large enough dose of the current. The experiments are also based upon the supposition that the fœtus is in the matter of vitality to be compared with some of the lower forms of life. Dr. Landis draws the following conclusions: 1. In using the faradaic current in extra-uterine pregnancy, the applications should be protracted for an hour, if the patient can bear it. 2. The current should be repeatedly applied, in order that the vitality of the fœtus may be finally exhausted. 3. The current should be used in great strength for at least one sitting. 4. The current probably acts, not only by destroying the fœtus, but by its action upon the placental circulation; an additional reason for a long application.

Bismuth as a Dressing for Wounds.—M. Gosselin and M. Héret ("Progr. méd.") have been studying the mode of action of subnitrate of bismuth upon wounds. It is known that this drug has the effect of diminishing the oozing of blood after an operation. Although, in itself, it has no coagulating power, it acquires such a property by virtue of the disengagement of nitric acid upon the mouths of the capillaries. Moreover, it has an astringent action, due at the same time to the nascent nitric acid and to the oxide of bismuth, a germicidal effect, and a special sedative operation. The subnitrate should be preferred, as the other salts have not, of course, the coagulating and constrictive power that is due to the acid. It may be used either in powder or by irrigation in the proportion of 1 to 50.

Formulæ for the Use of Iodoform.—"Nouveaux remèdes" quotes the following formulæ from the "Courrier médical":

An Injection for Chronic Catarrh of the Bladder, Urethritis, etc.—

Iodoform	1 part;
Glycerin	5 parts;
Distilled water	100 "

For Hypodermic Injections in Syphilis.—

Iodoform	1 part;
Sulphuric ether, Olive-oil, each	5 parts.

For Internal Use in Convulsions.—

Iodoform	18 grains;
Iodide of potassium	1 drachm;
Red wine	$2\frac{2}{3}$ drachms.

From three to fifteen drops are to be given, in a glass of wine, three times a day.

Pills for Bronchitis and Emphysema.—

Iodoform	$1\frac{1}{2}$ grain;
Lycopodium	6 grains;
Extract of phellandrium	15 "

Divide into ten pills. From three to five to be taken daily.

Chloroform in the Treatment of Post-partum Hæmorrhage.—Dr. F. Betz ("Memorabil.") was lately led by Robinson's reports of the efficacy of alcoholic injections into the uterus to try the effect of inserting a sponge saturated with chloroform. Severe burning pain was at once produced in the whole parturient canal, but brisk uterine contraction supervened promptly, and the bleeding was stopped. In another case he pressed against the cervix a tampon moistened with a mixture of chloroform, sulphuric ether, and a little acetic ether. The same results followed. The styptic action, he remarks, is wholly due to muscular contraction, and not at all to the coagulation of blood.

Belladonna as an Adjuvant to Iodide of Potassium.—Aubert ("St. Petersb. med. Wchnschr."; "Memorabil.") states that the use of belladonna prevents the unpleasant effects sometimes produced by iodide of potassium on the naso-pharyngeal mucous membrane. Three quarters of a grain of extract of belladonna, in pill form, given with the iodide, are sufficient, and the use of the adjuvant need not be continued long, for after a short time the disposition to the unpleasant effects referred to disappears and does not return.

Antimony in the Treatment of Psoriasis.—Mr. James Mason ("Glasgow Med. Jour.") says that in some of the most inveterate cases antimony "acts like a charm," causing a rapid disappearance of the scaling. He alludes to the case of a man whose face and head became almost entirely free from scales after a week's use of five-minim doses of wine of antimony. The author adds that the antimonial treatment of psoriasis has been practiced for several years by Dr. Cavafy, of St. George's Hospital, London.

Original Communications.

A CONTRIBUTION TO THE TREATMENT OF CERTAIN FRACTURES OF THE BONES OF THE LEG, AND OF THE PATELLA, BY DRILLING AND WIRING OF THE FRAGMENTS.*

BY J. WILLISTON WRIGHT, M. A., M. D.,

PROFESSOR OF SURGERY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF THE CITY OF NEW YORK; VISITING SURGEON TO BELLEVUE HOSPITAL, ETC.

MR. PRESIDENT AND GENTLEMEN: The following five cases of compound fracture of the bones of the leg, together with three of simple fracture of the patella, which I have treated during the past three years by drilling and wiring of the fragments, are presented, not so much with the view of taking a new departure in the management of this class of injuries as for the purpose of inviting a discussion of the subject at large, and with the object of determining, as far as may be from a limited amount of material, whether the method by wiring in the worst cases of compound fracture of the leg, and in certain exceptional cases of simple fracture of the patella, to which the plan has been restricted in my own practice, possesses any advantages over the older and more usual means of treatment, either in the way of greater safety to life, additional opportunities for avoiding an amputation, primary or secondary, in favoring the reparative processes, or, finally, in the direction of a saving of time and a mitigation of suffering for the patient.

CASE I.—John Sheridan, Irish, liquor dealer, aged twenty-seven, healthy.

February 6, 1884.—Was injured by street-car this morning, the wheels passing obliquely over the right leg near the knee. Compound fracture of the tibia, two inches below the tubercle, associated with a contused and lacerated wound, four inches long, extending upward and inward from the seat of fracture. Fracture exposed, under bichloride irrigation, by an incision four inches long, made parallel with the crest of the tibia, and communicating with the original wound. The fracture was found to be oblique from above downward and from within outward. Deep pockets, filled with coagulated blood and sand, extended upward in the subcutaneous tissue to above the knee joint, and downward for a distance of four or five inches. The fascia of the leg was extensively lacerated, the tibialis-anticus muscle badly torn and contused, and the periosteum stripped from the fragments of the bone for some distance.

The blood-clots, sand, and shreds of tissue were removed by washing, scraping, and the use of the scissors; the fragments drilled and wired together with a double strand of No. 26 silver wire.

The wounds were closed with carbolized catgut sutures; the pockets drained with rubber tubes through counter-openings; the limb was dressed antiseptically, and suspended in a cradle made of heavy wire netting.

18th.—Highest temperature since the operation 100·6°, and during the last week it has been normal. No pain. Dressing changed to-day for the first time (twelve days). No pus in the dressings. The incision made with the knife has healed throughout by first intention; a small linear dry slough is found on one edge of the original wound, where the skin was much contused; there is no swelling, no inflammation, and the leg looks remarkably well; drainage-tube removed, and the limb dressed as at first. From this time all went well; the remainder of the wound cleaned, granulated, and healed kindly, and the patient was discharged June 2d (sixteen weeks after the injury) with no shortening or other deformity, and able to walk well. Patient seen April 23, 1885, and says his injured leg is "nearly as good as ever."

CASE II.—Nellie Murphy, Irish, tailoress, aged thirty, good health.

Her left knee has been partly flexed and ankylosed for several years past, due to an old synovitis.

February 15, 1884.—Fell down stairs to-day and sustained a fracture of the left tibia just below the tubercle, compounded by an opening in the skin one inch in length; fracture slightly oblique, with considerable displacement of fragments. Another simple fracture of the same bone was discovered at the junction of the lower and middle third.

16th.—Under bichloride irrigation, an incision, three inches long, was made at the seat of the upper fracture, over the crest of the tibia.

The soft parts were not seriously lacerated, but considerable dissection of the connective tissue had taken place from a large amount of effused blood.

The wound was thoroughly cleared of clots and cleansed; the fragments were drilled and wired as in Case I. Wound closed with catgut, drained through counter-opening; limb dressed antiseptically and suspended.

In this case I ventured to predict delayed union of the upper fracture on account of its locality and from the fact of its being complicated by another fracture lower down, my experience in similar cases having taught me that any fracture at the upper end of this bone is less likely to unite promptly, *cæteris paribus*, than one in the middle of the shaft, due, probably, to its greater distance from the principal trunk of the nutrient artery; and, furthermore, that when a multiple fracture is present, the one which is nearest to the nutrient foramen will be the first to unite; or, in other words, the lower fracture, under these conditions, seems to appropriate to itself whatever reparative material is brought to the injured bone through this channel, leaving the upper fracture mainly dependent upon the small vessels which have first ramified in the periosteum before entering the bone.

17th.—Temperature 101·4°.

26th.—Temperature normal since last report. Dressings changed to day for the first time (eleven days). No pus; wound healed; tube removed and new dressing applied.

March 15th.—Dressing removed; union of fractures not firm; plaster splint applied.

Subsequent History.—The lower fracture united with slight deformity, owing to the impossibility of keeping the lower end of the middle piece in position, in about the usual time; but the union of the upper fracture was delayed for many weeks.

Patient discharged July 26th (five months after the wiring), able to support the weight of the body on the limb.

November 20th.—Union not absolutely perfect, but patient able to walk well by the aid of a cane.

* Read before the New York Clinical Society, April 24, 1885.

Case III.—Thomas Rafferty, Irish, laborer, aged forty-three, healthy.

July 21, 1884.—To-day, while working in a quarry, a heavy stone fell from a derrick, striking an iron bar which he held in his hand, and driving it, with great force, against his right leg. On examination, I found a small incised wound at the junction of the lower and middle third, on the inside of the leg, which communicated with a fracture of the tibia, and also with a large hæmatoma extending from the wound to below the internal malleolus. The patient had lost much blood and was still bleeding freely. Under irrigation, an incision was made, beginning two inches above the wound and curving downward to include it and the hæmatoma, four or five inches in length.

The fracture of the tibia was found to be oblique from above downward, forward, and inward, with some comminution of the bone; one fragment, one inch and a half in length, and several smaller ones were removed. The internal malleolus was denuded, bruised, and roughened; the sheath of the tibialis-posticus muscle was opened and the muscle itself badly torn; the connective tissue was lacerated and extensively infiltrated with blood; the fibula was fractured higher up, but not compounded.

The wound was cleansed, the hæmorrhage controlled, the fragments drilled and wired with heavy copper wire coated with silver, and the limb dressed like the others.

August 2d.—Highest temperature since the operation 100·8°.

11th.—First dressing to-day (twenty days). Wound healthy and healing, with the exception of a small dry slough at the center of old hæmatoma.

30th.—Redressed. Slough separated and wound nearly healed.

September 6th.—Wound healed and plaster splint applied.

24th.—Plaster splint removed; found twisted portion of wire protruding through a small ulceration of the skin; wire cut and removed; union not firm; percussed the bone above and below the seat of fracture with small rubber mallet. This was followed by a mild attack of simple cutaneous erysipelas, lasting two weeks, at the end of which time the union was found to be firm and bony.

Patient discharged, March 29th (eight months from the date of the injury), with good union of the fracture, but with some stiffness of the ankle joint, due chiefly to his great timidity in using the limb.

Case IV.—Henry Hall, American, wall-paper maker, aged forty-six; healthy.

February 22, 1885.—Fell in the street to-day while intoxicated and sustained a compound fracture of both bones of left leg, about three inches above the ankle joint. The fracture of the tibia was very oblique from above downward and inward, the fractured surfaces being four inches long and the ends of the fragments very sharp. Two small wounds of the skin, caused by puncture of the upper fragment, were found on the inner side of the ankle just above the malleolus. Under irrigation, an incision, five inches in length, was made to expose the fracture. There was much overriding of the fragments, and great difficulty in effecting reduction, even with the patient profoundly under the influence of ether, and it was impossible to maintain apposition except by powerful extension and counter-extension. A bleeding vessel of some size, probably the internal malleolar, was ligated. The fragments were then drilled and wired in two places with heavy silver wire. Dressing and after-treatment like the others.

March 16th (twenty-two days).—First dressing; wound nearly healed; highest temperature since the operation 100·4°. Applied plaster splint with fenestra opposite wound.

April 1st.—Wound healed; union pretty firm.

Discharged July 10, 1885 (twenty weeks), with good union; good position of foot; good motion in ankle joint and with no perceptible shortening of the limb.

Case V.—Leopold Marks, German, tinsmith, aged forty-three; healthy.

July 10, 1885.—A heavy slab of marble fell on his left leg to-day, producing a compound and comminuted fracture at the junction of the lower and middle third.

11th.—Under irrigation, an incision four inches long over the crest of the tibia showed the fracture to consist of five fragments. Its general direction was first from above downward and outward, then from above downward and inward, the two lines including a large wedge-shaped piece of bone, measuring three inches in length on its longest side, and including at its apex nearly the whole of the diameter of the bone. This, together with two smaller fragments, was found to be so completely isolated from all vascular supply that its removal from the wound was rendered necessary; in fact, the large fragment was turned upon itself so as to occupy an antero-posterior position with regard to the long axis of the tibia, while one of its sharp points had seriously lacerated the deep muscles of the leg and was lying in dangerously close proximity to the posterior tibial artery. Deep pockets, filled with clotted blood and reaching for two or three inches above and below the wound, were exposed and cleansed. The main fragments were then drilled in two places and brought together with heavy silver wire; the wound closed and drained through one of the bone punctures; the limb dressed antiseptically, and put up like the others.

The patient had no symptoms worthy of note. Dressings changed on the twelfth day, and the wound found healed; tube removed and limb redressed.

August 1st.—Plaster splint applied. Patient still under treatment.

Through the courtesy of Dr. L. W. Hubbard, formerly house surgeon to Bellevue Hospital, I am accorded the privilege of bringing to the notice of the society the prominent features of one of the most interesting and instructive cases of this kind which have ever fallen under my observation.

This case, in which I had the pleasure of assisting Dr. Hubbard, will be reported in full in the "New York Medical Journal" in connection with my own.*

Case I.—*Fracture of the Patella.*—Henry Vilner, Hebrew, peddler, aged twenty-four; feeble health, badly nourished.

June 9, 1883.—Patient was knocked down in the street to-day and sustained a transverse fracture of the right patella. When admitted to the hospital there was a large effusion of blood into the joint, with great swelling and ecchymosis. The fragments of bone were separated about three inches, and it was impossible to approximate them at any time. He was treated with cold applications, ice to the joint, position, and various forms of apparatus without benefit until July 12th, when the joint was opened, under irrigation, by a crucial incision, and thoroughly cleaned out. The fractured surfaces were then scraped, the fragments drilled and wired, and the joint drained. The wound was then closed with a continuous suture of carbolized catgut, the limb dressed antiseptically, and the knee joint immobilized. The operation was followed by some sloughing of the edges of the skin-wound and by the formation of a circum-articular abscess; but all eventually repaired, and the patient was discharged, October 1st (sixteen weeks after the injury), with bony union of the patella, able to walk well, and with about twenty degrees of motion in the joint.

* Brief history of case given.

Patient seen eighteen months after the injury, with full motion of the joint, with perfect bony union of fragments, and he stated that he had walked twenty miles the day before without inconvenience and without artificial support of any kind.

Case II.—*Fracture of the Patella.*—James Klein, German baker, aged forty-five; healthy.

January 9, 1885.—Fell in the street to-day, striking the bent right knee on a stone and fracturing the patella transversely. The joint was greatly distended with blood and very painful. I was unable to determine the exact nature of the fracture on account of swelling and effusion.

The limb was suspended and treated with cold applications.

February 2d.—Knee still very much swollen, hot, tender, and painful, and I fear a suppurative inflammation of the joint.

Opened joint, under irrigation, by a crucial incision.

The capsule of the joint and the aponeurotic structures were all extensively lacerated, with their ragged edges turned into the cavity of the joint. The patella was fractured transversely about its middle, with the upper fragment split longitudinally into two portions, but not entirely separated from each other, while three smaller fragments were found loose in the joint. The cavity of the joint was enormously distended with clots, in which the main fragments were deeply buried.

The joint was thoroughly cleaned, the fragments drilled and wired in two places; the capsule and aponeurosis trimmed and sewed up with fine catgut; the skin-wounds closed separately in the same way, and the joint drained. Antiseptic dressings were then applied, and the limb suspended in a wire cradle.

14th.—First dressing (twelve days); wound healed; no fluid in the joint; tubes removed and new dressings applied. Highest temperature since the operation, 100·2°.

28th.—Fragments in good position and apparently united; applied plaster splint. Discharged about the middle of March.

April 22d (twelve weeks after injury).—Can bend knee to right angle, and union seems to be perfect. Walked ten miles with cane two days ago.

Case III.—*Fracture of the Patella.*—J. H., laborer, American, aged thirty-three, healthy.

June 10, 1885.—Six months ago patient was thrown from a wagon and sustained a transverse fracture of the right patella. The knee joint is now nearly useless; the fragments are three inches apart, and apparently held together by a very thin fibrous band. Joint opened under irrigation; the fractured surfaces freshened, and the fragments drilled in two places, wired, and the limb put up like the others. The patient had no constitutional disturbance whatever as a result of the operation. At the end of ten days the wound was dressed and found healed throughout; drainage-tubes removed and joint redressed.

29th.—Limb put up in plaster splint.

Patient left hospital about the middle of July, still wearing splint, but apparently with good bony union of the fragments.

The chief points of interest in these cases are, first, the facility which the method affords for the removal of blood-clots, foreign bodies, and torn tissue, thereby leaving a comparatively clean wound, which is likely to repair with little, if any, suppuration or sloughing, provided the operation is done antiseptically.

Secondly, the ability which it gives the surgeon to effect a complete and immediate reduction of the fracture, and the subsequent maintenance of the fragments in perfect apposition by means of the wire suture—an important indication, and one which it is impossible to fulfill in many cases by other means; and the consequent avoidance of such irritation of surrounding soft tissues as must necessarily occur when rough fragments of bone are allowed to move more or less upon each other.

Thirdly, the avoidance of frequent dressing, which always necessitates the disturbance of the reparative processes to a greater or lesser extent with each repetition; the increased probabilities of speedy union when the fragments are securely put together and held in apposition during the whole course of the treatment, not to mention the saving of pain for the patient, and of time and trouble for the surgeon.

Fourthly, and perhaps most important of all, the ability which the method gives to the surgeon to save certain limbs, the seat of bad forms of compound fracture, which would otherwise seem to demand primary amputation, or which, if treated in any other way, might seriously endanger life from prolonged suppuration, sloughing of soft parts, necrosis, osteo-myelitis, septicæmia, pyæmia, etc.

A CASE OF COMPOUND FRACTURE OF THE TIBIA TREATED BY WIRING.*

By LEROY W. HUBBARD, M. D.,
LATE HOUSE SURGEON TO BELLEVUE HOSPITAL.

F. L., aged thirty-six years, native of Germany. Patient was admitted to the hospital about midnight May 15, 1884, having been transferred from another institution in the city. The following history was obtained: Four days ago he had fallen through the floor of a new building and sustained a compound fracture of the left tibia. At the time of his admission to Bellevue the man was in an active delirium, presenting the usual symptoms of delirium tremens. As the limb appeared to be well supported and dressed, it was deemed advisable not to disturb it before attempting to control the delirium.

May 16th.—Less troublesome to-day, though still delirious. Temperature somewhat elevated, and pulse rapid and compressible.

During the evening it was discovered that considerable hæmorrhage had taken place, and, as the patient was now quiet, the dressings were changed. On exposing the leg, the fracture was found to be very oblique and situated about three inches above the inner malleolus. Owing to the displacement of the fragments, the sharp point of the upper piece had again punctured the skin, making an additional wound. The skin for several inches around the seat of fracture was dark and had a sloughy appearance. Several free incisions were made in it, and drainage-tubes inserted. All hæmorrhage had apparently ceased, and the leg was redressed with a thick antiseptic dressing and supported by side-splints.

17th.—The patient was etherized and examined by Dr. Stephen Smith, Dr. J. W. Wright, and several of the hospital staff. On removing the dressing, it was found that venous hæmorrhage had taken place, and a large, soft clot lay between the dressing and the skin; that the connective tissue of the entire limb from the ankle to the knee was extensively infiltrated with blood, and the leg presented the appearance of the first stage of moist gangrene. Indeed, it seemed almost hopeless to make the attempt to save it, and I have no doubt that a few years ago almost any surgeon of experience would have advised immediate amputation at the knee joint as the only probable means of saving the patient's life. Influ-

* Presented, by permission, by Dr. J. Williston Wright with his paper read before the New York Clinical Society, April 24, 1885.

enced, however, by the excellent results previously obtained by wiring severe compound fractures in several other cases occurring on the division, it was determined to try what conservative surgery under strict antiseptic methods would accomplish. The seat of the fracture was exposed; the clots of blood surrounding it were removed; the lacerated connective tissue, sheaths of muscles, etc., trimmed; and the fragments brought into apposition as nearly as possible and held together by a suture of silver wire passed through holes drilled in the bone near the margins of the fracture. A free incision was then made on each side of the leg down to the muscles, extending from the seat of fracture to just below the knee. All of the clots of blood were removed by scraping and irrigation. The incision on the inner side was then closed partly with deep silver wire and partly with superficial catgut sutures, drainage-tubes being placed at various points. The incision on the outside was left open on account of tension. During the whole of the operation continuous irrigation with a solution of hydrarg. bichlor., 1 to 2,000, was employed. The wounds were dusted thickly with iodoform, and the limb was dressed with pads of carbolized gauze and borated cotton, and supported with side-splints held by turns of a carbolized bandage.

The patient rallied well from the operation, and had no more delirium from that time. The temperature rose the next day to 102·5°, but after that was never above 101·75°, and by the fourth day was normal.

19th.—The limb was placed in a posterior wire cuirass and suspended.

June 5th—Nineteen days after the operation.—Dressing changed for the first time. The incision on the inner side was nearly healed throughout; the granulations on the other side were healthy and secreting laudable pus.

The fragments were in very good apposition, and granulations had begun to cover the surface of the bone. The leg was subsequently dressed every seventh or eighth day, and each time was found much improved.

July 19th.—A plaster splint applied, and patient allowed to sit up.

October 1st.—Walking about the ward supporting himself with a crutch.

December 17th.—Discharged from the hospital with wounds healed, good union of fracture, able to walk well, and with only a slight amount of shortening.

130 West Twenty-first Street.

CONTAGIOUS CONJUNCTIVITIS; ITS CAUSES, PREVENTION, AND TREATMENT.*

By JOSEPH A. ANDREWS, M. D.,

MEMBER OF THE AMERICAN OPHTHALMOLOGICAL SOCIETY; OPHTHALMIC SURGEON TO CHARITY HOSPITAL, NEW YORK, ETC.

(*Concluded from page 452.*)

Prophylaxis of Ophthalmia Neonati.—Starting from the proposition that the infection of this disease is derived, in the first instance, from a pathological vaginal secretion from the mother, thorough and judicious cleansing of the diseased vagina should be practiced before the birth of the child, and, when the child of such an infected mother is born, its eyes should be washed with a saturated solution of boric acid, and a two-per-cent. solution of nitrate of silver be dropped into the conjunctival sac; and the child and mother should not alone be kept from other children, but the mother should be told of the contagious character of her disease and warned against using towels, sponges, or cloths that have been used on her own person, for wiping her child.

The eye-trouble begins about the second or third day after birth, also sooner or later; the sooner, the more intense it will be, generally.

Credé first tried thorough cleansing of the diseased vagina of the mother before the birth of her child. The number of cases of eye-trouble was diminished thereby, but it did not disappear. Then he began to disinfect the eyes of the children, and the results were more favorable. This is quite natural, because, if the child is infected at the time of its birth, no amount of attention bestowed upon the mother would affect the child so long as it was neglected. At first Credé proceeded as follows: In all cases of gonorrhœa or chronic vaginal catarrh in the hospital, the vagina was frequently washed with lukewarm water, or a solution of carbolic acid, or salicylic acid, two per cent.; near term this was done every half-hour. The eye-trouble was less frequent, but it was not stamped out. In 1879 he made the first trial of prophylactic instillations into the eyes of the new-born immediately after birth, and used a solution of borax (1 to 60) without satisfactory results.* Then he tried a solution of nitrate of silver (1 to 40), which was dropped into the eyes soon after birth. These instillations were preceded by careful washing of the eyes with a solution of salicylic acid (two per cent.). Children thus treated remained free from eye-trouble. From June 1, 1880, all eyes, without exception, were, immediately after birth, first washed with plain water and disinfected with a solution of silver nitrate (two per cent.), a single drop being placed in each eye; then the eyes were cooled with pledgets of linen wet in a solution of salicylic acid (two per cent.). The vaginal douching was, on the contrary, discontinued. Only one child, on the sixth day, had a mild conjunctivitis of the left eye, without swelling of the eyelids, and was cured in three days. It was shown in this case that in the hurry the prophylactic instillations had not been made. Sometimes a slight hyperæmia followed these instillations, and now and then there was a slightly increased secretion in first twenty-four hours; these appearances do not persist after the first day. Previous to the introduction of this treatment in Credé's clinic at Leipsic ten per cent. of the children born there had eye-trouble; since its employment, from June 1, 1880, till March, 1883, the percentage was reduced at once:

1880 (7 months),	211	children,	1 case;
1881	400	"	1 "
1882	418	"	2 cases;
1883	131	"	No case.
	1,160		

The patient in 1880 was not disinfected. The mother, in one of the two cases which occurred in 1882, had syphilis and gonorrhœa, and what is of interest to us to remember in this connection is that, in spite of the instillation of silver nitrate (two per cent.) immediately after birth, it was too late. Credé says that the other case (1882) resembled one of catarrhal conjunctivitis.

* "Archiv f. Gynäkol.," 1881, Bd. xvii, p. 52.

Abegg* washed the eyes with pure water immediately after birth. The result was that among 2,266 births there were 66 cases of ophthalmia neonatorum, or about three per cent.

At the suggestion of Alfred Graefe, Olshausen† used a one-per-cent. solution of silver nitrate, without previously washing the eyes, and reduced the percentage of ophthalmia neonati from 12·5 to 6 per cent.; but he observes that *the percentage would have been even smaller had the measures been more exactly practiced from the beginning.*

Hecker (München) used a one-per-cent. solution of silver nitrate as a prophylactic, but he had about as many cases as before, and Credé's criticism upon these results is that one per cent. is not sufficiently strong.

In Maternity Hospital, Blackwell's Island, New York, Dr. Garrigues applied a two-per-cent. solution of silver nitrate to the eyes of all the children born during his service at that institution from October 1, 1882, to March, 1883, and from October 1, 1883, till March 31, 1884, during which time 351 children were born, but not a single case of eye-trouble occurred among those children. Dr. Garrigues does not state whether any of the mothers were infected or not. At the same hospital, in Dr. Mundé's service, the house surgeon, Dr. B. Hughes Wells, informs me that between April 1 and May 15, 1885, 83 children were born, all of whom were treated with silver nitrate (two-per-cent. solution), there being not a single case of eye-trouble. In the six weeks preceding Dr. Mundé's service (Dr. Murray's service) 58 children were born. In this instance a one-per-cent. solution of silver nitrate was used, and there were more than 10 or 12 cases of ophthalmia neonati, but none of these cases led to loss of sight; only in one case was there ulceration of the cornea, and in this the latter was not perforated.

Horner‡ indorses Credé's treatment with silver as the most effective. In the discussion on Dr. Horner's paper, the expediency of employing this treatment in private practice was questioned. It was said that the eversion of the lids should not be intrusted to a midwife, because she might drop the solution on the cornea and damage it. Credé replied that he never everted the lids, because he deemed this superfluous; he dropped the silver solution (two per cent.) on the cornea without having seen a single case in which this cauterized the cornea.

Königstein# observed, among 1,092 children in Späth's clinic for whom no prophylactic measures had been adopted, blennorrhœa in 4·76 per cent.; catarrh in 14·5 per cent. He adopted Olshausen's plan of washing the eyes frequently with a solution of carbolic acid, one per cent. Of those thus treated, two per cent. had blennorrhœa and six per cent. catarrh. Finally, of 1,300 children treated according to Credé's method, one half per cent. had blennorrhœa and six per cent. catarrh.

Felsenreich, in the clinics of Carl and Gustav Braun, reduced the percentage of blennorrhœa by Credé's treatment from 3·34 to 1·93 per cent.

In 1881, Bayer* treated 361 children at the Stuttgart Lying-in Hospital according to Credé's plan, and there was not a single instance of eye-trouble; while in 1880, among 354 children born at the same institution, there were 34 cases, and in 1879, among 351 children, there were 51 cases of ophthalmia neonati, no prophylactic treatment having been then employed.

At the Royal Lying-in Institute in Dresden, Credé's treatment was introduced on October 1, 1883.† The instillations were made about a quarter of an hour after birth, after the child had been washed and its eyes cleansed with a piece of linen dipped in fresh water. In a few cases, in the confusion occasioned by many births occurring in quick succession, the instillations were made somewhat later. From October 1, 1883, to July 10, 1884, 1,002 live children were born. Uncleanliness, intense elytritis, and granular elytritis were present in numerous instances, and other influences were also noted which might have contributed to favor a blennorrhœal infection in the children, but not a single case of blennorrhœal conjunctivitis occurred.

Credé's treatment, with its instillations of a two-per-cent. solution of silver nitrate, and especially the additional applications for twenty-four hours of a solution of salicylic acid (two per cent.) on pledgets of linen, involves a strict personal supervision which must be counted. But the evidence, taken all in all, certainly proves the value of a two-per-cent. solution of silver nitrate as a prophylactic in ophthalmia neonatorum; yet it should not be used to the exclusion of scrupulous cleanliness.

In order to guard against post-natal infection—which, as I have said, I believe to be more common than that at the time of birth—children should be kept in their cots and not given to the mother (if she is infected) except at the time of nursing, and then all the precautions respecting the use of sponges, towels, etc., should be kept in mind.

If it is possible, by the means indicated, to cut down the percentage of cases of ophthalmia neonati so impressively as the statistics cited above would seem to prove that we can, it is quite impossible to exaggerate in words the importance of the gain.

Horner has shown that, among 100 blind asylums of Germany and Austria, between 33 per cent., or, to be more exact, between 20 per cent. and 79 per cent. of the blind children had lost their sight from ophthalmia neonati.

In a statistical report submitted to the Blind Congress in Paris, in 1879, F. Daumas declared that, of 56,391 eye-patients treated by himself, 1,178 had become incurably blind, 108 cases of blindness being due to incurable disease and 1,070 to curable disease.

In the United States, ophthalmia neonati causes blindness in numbers exceeding 32 per cent. of the cases of preventable diseases of the eye.

Now, inasmuch as blindness from the disease under consideration occurs mainly among the poor, and is due chiefly to ignorance regarding its dangerous character and the consequent neglect to apply prompt and effective medical aid, it behooves the profession to draw general attention, and

especially that of midwives, to this very important subject. Our general dispensaries might substantially aid the dissemination of this desired intelligence by having conspicuously printed on the card presented to every female patient who applies for medical aid the following Instructions regarding New-born Infants:

"*If the child's eyes become* red *and* matter *begins to* run *from them, at any time after birth, take the child at once to a doctor.* The disease is very dangerous, and, if not treated at once, it may destroy the sight of both eyes."

Let me now give you an outline picture of purulent conjunctivitis as it is but too frequently seen at our eye-infirmaries. The mother takes her child to the infirmary with the statement that the child's eyes had "run matter" for some days; but the eyelids had become so red and swollen, and the child so restless, that she thought she had better take it to the hospital. We examine the eyes and find a large slough of one or both corneæ, and the sight of one or both eyes destroyed. Every eye-surgeon has seen many such cases. Could a stronger reason be given for the urgency of sending out words of warning to these unfortunate people? A mother would not neglect early attention to her child with this disease if she knew how terrible the consequences would be of so doing. The next question is, How shall we treat such cases? To return such a child to its own home would be to expose the rest of the family to the disease; and, again, such patients are brought to us at the infirmaries three times weekly; they then return daily to their homes, where the ignorance of the simplest rudiments of personal and domestic hygiene which invariably prevails there must necessarily neutralize whatever good they may have received at the hospital; indeed, patients with this disease require to be under skilled and constant surveillance; and, if our eye infirmaries will not receive these cases because of the danger of infecting their other patients, the exigencies of the case are best met by the establishing of a separate hospital for the treatment of contagious ophthalmia.

In Great Britain steps were taken last year in the direction of making efforts to prevent the terrible consequences of ophthalmia in the new-born, and it is hoped that the committee appointed for the same purpose at the last meeting of this Academy will succeed better than our colleagues across the Atlantic in carrying out the plans they may agree upon to meet the end in view.

Treatment.—The attendant's hands and nails must be thoroughly cleansed and his or her eyes protected with *protective spectacles.* If one eye only is affected, its fellow should be sealed with cotton-wool, covered with adhesive plaster, and over this a solution of rubber should be painted, so as to exclude any discharge which may run over the bridge of the nose from the affected eye, and, in the case of infants, the hands should be secured, in order to keep them from the eyes. In the case of adults, a far better protective covering for the healthy eye is one recommended by Dr. Buller, of Montreal, which consists of a piece of macintosh, about four inches and a half square, with a watch-glass (old-fashioned, deep glass) fastened to a hole in the center through which the patient can see; the whole is then fixed by broad pieces of strapping to the nose, forehead, and cheek, its lower and outer angle being left open for ventilation. In case of redness or swelling of the conjunctiva, this covering must be discontinued and the conjunctiva painted, as a preventive, with a two-per-cent. solution of silver nitrate, followed by cold applications.

So long as there are increasing redness and swelling of the eyelids, together with rising temperature of these parts, and a watery or sticky, transparent secretion, which shows that we have to do with a pure inflammation, the treatment must be anti-inflammatory, directed to the contraction of the paralytic vessels, and thereby diminish the filtration and diapedesis; and the remedy is the same in the case of the eye as in other parts of the body. The ice-cloths should be applied, and, according to the height of the local temperature, their use should be more or less vigorous; but, *under all circumstances, the cold applications must be diligently changed,* in order that the action of the cold may be as nearly as possible equable. When the local heat is very great, the cold must be maintained day and night.

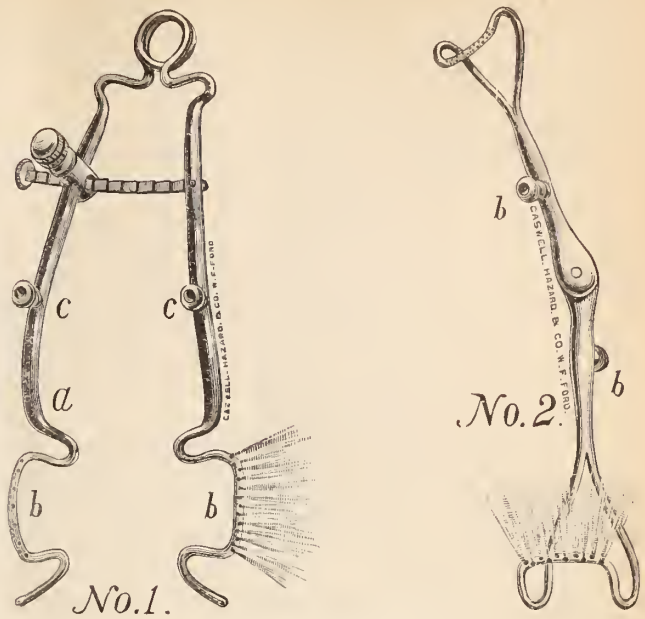
When purulent conjunctivitis is fairly established, the indications for treatment are: 1, to wash away the infective material as thoroughly and as early as possible; 2, to render the conjunctival surface as nearly as possible aseptic. It is impossible to exaggerate the importance of securing a perfect fulfillment of the first of these conditions. If the disease is seen at the very onset, and the eye cleansed at once, its course will be less violent than where this is not done. This washing may be done with a saturated solution of boric acid, or a two-per-cent. solution of carbolic acid, the latter to be weaker as the discharge grows less. The eye must, of course, be carefully examined for any change in the cornea. It is not necessary that we should employ our solution in sufficient strength to be germicidal. The ordinary method adopted in purulent conjunctivitis of washing the eye with a so-called antiseptic fluid does not kill the bacteria in the secretion, but removes the contagious principle as completely as may be, or so dilutes it that it can do harm only in a less degree; and it will be found that the secretion actually decreases in proportion to the disappearance of the cocci from it. I think that for this reason the irrigation should be maintained for several minutes at a time—ten to fifteen minutes. I would then paint the conjunctival surfaces of the upper and lower lid with a two-per-cent. solution of silver nitrate, or even twelve per cent. if the conjunctiva is much swelled; and, in case the latter strength is used, wash afterward with a solution of sodium chloride. The strength of the silver solution is to be regulated by the succulence and vascularity of the conjunctiva—the more pronounced these conditions, the stronger should the solution be. This having been done, *cover the conjunctiva with an antiseptic dressing consisting of boric acid (six per cent.) or carbolic acid (two per cent.) and vaseline.* The vaseline will be retained much longer than a watery solution would be. This dressing will, in a great measure, have the power (without injury to the cornea) of arresting the vital activity of the bacteria, of starving them out, as it were, by so changing the nutritive pabulum required for their development that they can not appropriate

it to their use. The irrigation will have to be repeated as often as may be indicated by the quantity and quality of the discharge. If there is much swelling of the eyelids, the outer canthus should be cut. The application of cold should not be made with ice-bags. Pledgets of linen—to be burned after use—should be laid on a piece of ice at the bedside, and this application of cold requires care and a constant attendant.

In the severe forms of gonorrhœal conjunctivitis—and this disease is nearly always very severe—when not seen very early and treated at once, the cornea runs great risk. The eyelids are intensely swollen, and when the ocular conjunctiva is much infiltrated the cornea is in great danger of suppuration, and the treatment should be directed to the reduction of the pressure on the eyeball and diminution of the secretion already formed. The pressure caused by the chemosis and swollen lids compresses the vessels which supply the margin of the cornea, causing an insufficient circulation. In order to remove this factor, the outer commissure should be divided to its fullest extent, together with the canthal ligament. The late Mr. Critchett, of London, proposed to divide the upper lid vertically to the orbital margin in severe cases, evert the flap and fix it to the skin above, and he says the cornea does not suppurate when this is done. Fuchs* has modified this operation. He divides the outer commissure to such an extent as to relieve also the symptoms of pressure. He then puts a suture through the lower lid and attaches it on the cheek, ectropionizing it entirely. He detached the suture, in the case he reports, at the end of the fifth day, and the healing was good. If the cornea is involved, it requires special attention in addition to the use of atropine. A thorough removal of the secretion from the upper *cul-de-sac* is not possible by the ordinary means; this may, however, be done by means of a simple instrument which I have devised for the purpose. The instrument is an eye-speculum, the arms of which are hollow and the claw deeper than in the ordinary eye-speculum; it has a number of perforations for the passage of the fluid, which is supplied by a fountain syringe. It is inserted between the lids with great gentleness, and care should be taken not to injure the cornea with it. The lids should be gently lifted from the eyeball by means of the speculum, and the spray of fluid allowed to play upon the upper *cul-de-sac*. Even when the lids are extremely painful, it is a relief to have them gently lifted from the eyeball and the stream of fluid allowed to play upon the upper conjunctival *cul-de-sac*.

Of course the use of this instrument should not be intrusted to an ordinary nurse, but the physician can at least perform the operation twice daily, and keep up the irrigation for from ten to fifteen minutes. The solution of carbolic acid in the case of adults, when the inflammation is intense, may be as strong as three per cent.—to be diluted as the disease improves; this is astringent as well as antiseptic. And the silver I would apply, according to the exigency of the case, in four-per-cent. or twelve-per-cent. solutions, and neutralize with salt and water, and then apply the medicated vaseline to the conjunctiva, and over the lids the iced cloths. Iodoform has not met with much favor in this disease. Quinine in solution has also been used, but it has no advantage over the carbolic acid. Dr. H. Linds Ferguson (Dublin) reports cases of gonorrhœal conjunctivitis in which he has had good results from the use of finely powdered boric acid. The bichloride of mercury has no claim to advantage over the boric acid.

* "Centralblatt f. prakt. Augenheilkunde," 1881, p. 198.



The instrument shown in Fig. 1 may be used for either eye, the tube with the water-supply being attached at *c*, and to the upper branch only in case it is desired to irrigate the upper *cul-de-sac* alone. Fig. 2 represents a folding lid-elevator (of large and small size) designed for the same purpose as the spring-speculum. The tube of the fountain syringe is attached at *b*.*

Diphtheritic Conjunctivitis.—Measures of prophylaxis based upon bacteriology must lie in the future. We must be content with the enforcement of general hygienic laws. Mr. Tweedy† used one-per-cent. solutions of quinine in this disease, and did not see any serious damage to the cornea when it was used. Iodoform does not seem to be of much use in diphtheritic conjunctivitis. Vossius‡ recommends a four-per-cent. solution of salicylic acid in glycerin.

SPINAL ANÆSTHESIA AND LOCAL MEDICATION OF THE CORD.

By J. LEONARD CORNING, M. D.

It is my desire on this occasion to draw attention to a procedure in therapy which, so far as I am aware, possesses the merit of novelty. The arguments which I shall advance in its favor are twofold in kind: First, I shall cite certain physiological facts with which the procedure in question stands in immediate relationship; and, secondly, I shall endeavor to record conscientiously the actual phenomena evoked by the use of the method itself.

To take up the argument in this order, I would remark, then, that, when a certain quantity of a remedy, say strych-

* These instruments are made by Mr. W. F. Ford, of Messrs. Caswell, Hazard & Co.

† London "Lancet," 1882, No. 1.

‡ "Klin. Monatsbl. f. Augenheilk.," Bd. xix, p. 423.

nine, is thrown under the skin of a frog, certain phenomena make their appearance which show indubitably that the functions of the spinal cord are profoundly affected. The animal is thrown into violent convulsions, and assumes a rigid attitude, and we have presented the picture of an artificial tetanus. This is a spectacle of the physiological laboratory, and one with which we are all familiar.

If, now, we remove the posterior arches of three or four of the vertebræ of the animal, and, seizing the membranous coverings of the cord, insert the end of a hypodermic needle so that we are able to inject a small quantity of a solution of strychnine, we shall find, first, that not only are the convulsive phenomena immediately produced, but, secondly, that a smaller quantity of the fluid is required to evoke them than when the drug is placed under the skin at a point remote from the spinal cord.

It was formerly supposed that this phenomenon was due to the direct contact of the strychnine with the nervous elements of the cord, but Harley * has shown that the poison can act only through the intermediation of the blood-vessels, since, when the latter are separated from the cord, the solution remains entirely inert, the convulsions failing to appear.

From the foregoing considerations, it is clear that, in order to obtain the most immediate, direct, and powerful effects upon the cord with a minimum quantity of a medicinal substance, it is by no means necessary to bring the substance into direct contact with the cord; it is not necessary to inject the same beneath the membranes, as in the case of the frog, since the effects are entirely due to the absorption of the fluid by the minute vessels. On the other hand, in order to obtain these local effects, it is first necessary to inject the solution in the vicinity of the cord, and, secondly, to select such a spot as will insure the most direct possible entry of the fluid into the circulation about the cord. Is there in man a locality which fulfills these conditions? Instead of answering this question at once, I will rather detail some recent experiments performed by myself, by means of which, I trust, all doubts on the subject will be effectually set at rest.

Protocol of Experiments.—Some time since I began a series of experiments with a view to determining whether the local medication (anæsthetization) of the spinal cord was within the range of practical achievement. The drug made use of was the hydrochlorate of cocaine. As the introduction of a hypodermic needle beneath the membranes of the medulla spinalis is not practicable without removal of the arches of the vertebræ (on account of the danger of wounding the cord), I decided to inject the anæsthetic between the spinous processes of the lower dorsal vertebræ. I was led to resort to this expedient from a knowledge of the fact that in the human subject numerous small veins (venæ spinosæ) run down between the spinous processes of the vertebræ, and, entering the spinal canal, join the more considerable vessels of the plexus spinalis interna. From these theoretical considerations I reasoned that it was highly probable that, if the anæsthetic was placed between the spinous processes of the vertebræ, it (the anæsthetic) would be rapidly absorbed by the minute ramifications of the veins referred to, and, being transported by the blood to the substance of the cord, would give rise to anæsthesia of the sensory and perhaps also of the motor tracts of the same. To be more explicit, I hoped to produce artificially a temporary condition of things analogous in its physiological consequences to the effects observed in transverse myelitis or after total section of the cord. I therefore anticipated a more or less local action of the drug upon the cord. My hopes in this regard were based somewhat upon the well-known lethargy of the circulation in the cord, particularly at its lower portion—a condition of things highly promotive of the local action of the drug.

Experiment I.—This was performed on a young dog. At ten o'clock, A. M., I injected twenty minims of a two-per-cent. solution of the hydrochlorate of cocaine into the space situated between the spinous processes of two of the inferior dorsal vertebræ. Five minutes after the injection there were evidences of marked inco-ordination in the posterior extremities; the dog threw his hind-legs about aimlessly, holding them far apart, much after the manner of some ataxic patients. A few minutes later there was marked evidence of weakness in the hind-legs, but there were no signs whatever of feebleness in the anterior extremities. I now tested the condition of sensibility by means of a powerful faradaic battery, one of the conducting cords of which was attached to a fine wire brush. When the wire brush was applied to the hind-legs, there was no reflex action whatever on the part of the latter, at least such was the case except when the most powerful currents were employed. But, on the other hand, when I applied the wire brush to either of the anterior extremities, the limb was drawn away violently, and the animal set up the most dismal howls. Similar effects were observed on pinching and pricking the limbs.

These phenomena persisted for a considerable length of time, and traces of inco-ordination were observed two hours after the injection had been made. After the lapse of about four hours, however, the dog seemed to have recovered his usual health, and walked about without difficulty.

During the duration of the experiment nothing of an abnormal nature was observed in the fore-legs. I infer from this fact that the action of the anæsthetic was practically local, being confined, for the most part, to that portion of the cord situated immediately beneath the point of injection. It is conceivable, however, that, had the quantity of anæsthetic fluid injected been greater, the anterior limbs might also have been affected. An *absolute* localization of of the anæsthesia is indeed hardly within the range of possibilities, on account of the numerous blood-vessels. It is true, nevertheless, as we have seen, that the local action of the drug is greatly favored, at least so far as the inferior segment of the cord is concerned, by reason of the lethargy of the circulation at this point.

Experiment II.—This was performed on a man who had long been a sufferer from spinal weakness and seminal incontinence, and who for many years had been addicted to masturbation and other forms of sexual abuse. Without entering into the details of the case, which are devoid of any special interest, I will proceed at once to give an account of the experimental observation which constitutes its only claim to attention.

As in the case of the dog previously referred to, I was bent upon abolishing reflex action and annulling sensory conduction

* "A Hand-book of Therapeutics," by Sydney Ringer, M. D., New York, 1870, p. 387.

in the cord. To this end I injected thirty minims of a three-per-cent. solution of the hydrochlorate of cocaine into the space situated between the spinous processes of the eleventh and twelfth dorsal vertebræ. As there was no numbness, tingling, or other evidence of modified sensibility after the lapse of six or eight minutes, I again injected thirty minims of the solution at the same spot and in the same manner. About ten minutes later the patient complained that his legs "felt sleepy"; and, on making a careful examination with the wire brush, I found that sensibility was greatly impaired. Currents which caused lively sensations of pain and reflex contractions in the upper extremities were disregarded and barely perceived in the lower limbs. The same was true of the prick of a needle. Fifteen or twenty minutes later the anæsthesia had increased in intensity, and, although there were some evidences of diffusion on the part of the anæsthetic, the impairment of sensibility was principally limited to the lower extremities, the lumbar regions, the penis, and the scrotum. About this time I applied the wire brush to the soles of the feet and to the toes, using about the maximum strength of a powerful faradaic battery, without causing either pain or reflex contractions, while a current of half the strength evoked intense pain and reflex contractions in the upper limbs. Some time later I fancied that I could discern some obtuseness of sensibility in the upper limbs; but on this point I feel compelled to speak with reserve. When the patient closed his eyes he experienced some dizziness while standing, but there was no inco-ordination or motor impairment discernible in the gait. The power of distinguishing differences in pressure seemed also to be preserved; but I regret to say that I did not test the sensibility to variations of temperature. The passage of a sound, though usually accompanied by considerable pain, remained almost unperceived, and an urethral electrode caused no inconvenience, even when strong currents were used. The sensibility of the scrotum and glans penis was also impaired to a marked degree, as proved by repeated tests with the electric brush. The pupils were but slightly dilated.

When the patient left my office, an hour or more after the injections, sensibility was still impaired to a marked degree, but otherwise he seemed none the worse for his experience. The patellar tendon reflexes were, however, abolished.

The therapeutic advantages afforded by such local medication would seem to be great in a large number of morbid conditions of the cord. There is, indeed, no reason why strychnine and other remedies should not be employed in this local manner as well as cocaine. In strychnine poisoning, tetanus, and hydrophobia, it should also render good service. I will merely add that on the morning succeeding the injections the patient informed me that he had experienced tingling sensations and numbness in the lower limbs until nightfall. There was also dryness of the throat and mouth, accompanied by mental exhilaration. I could hear nothing of any cardiac disturbances.

On making an examination with the electric brush, sensibility was found to be normal in the lower limbs, scrotum, and glans penis. The passage of the sound was, as formerly, accompanied by some pain, and the urethral electrode provoked unpleasant sensations, even when mild currents were employed.

The only constitutional symptoms complained of were headache and slight vertigo, already referred to. At no time was there nausea.

Whether the method will ever find an application as a substitute for etherization in genito-urinary or other branches of surgery, further experience alone can show. Be the destiny of the observation what it may, it has seemed to me, on the whole, worth recording.

26 West Forty-seventh Street, *October 27, 1885.*

SEASICKNESS AND ITS TREATMENT.

By ADOLPH KESSLER, M. D.,
NEW YORK.

In the "New York Medical Journal" of September 20th I find a therapeutical note, taken from the "Berlin. klin. Wochenschrift" and "Lancet," in which Manassein recommends the use of cocaine in seasickness, and speaks of the gratifying results obtained in several cases. Unaware of the fact that it had been recommended and used in seasickness, I gave it a pretty extensive trial this summer, merely prompted by its general physiological and anæsthetic effects, but with results far from gratifying. It does not act as a palliative, much less as a curative; on the contrary, its use does actual harm. The effect of cocaine upon seasickness, as a combination of the most varied bodily and mental sensations, is purely negative, except for a decided increase and aggravation of certain symptoms. The most striking effect of the medicine is an intense and persistent nausea, which becomes the more distressing as all efforts, mechanical or otherwise, of obtaining relief by vomiting prove unavailing. Now, any one that has ever suffered the pangs of seasickness will agree with me that this very nausea, *unrelieved by vomiting*, forms the most distressing and depressing feature of the mysterious disorder, and that the act of vomiting is the only efficacious means by which temporary relief is afforded and comparative physical and mental comfort restored to the sufferer.

The cocaine seems to exercise a paralyzing influence upon the motor-nerve apparatus of the stomach, thereby hindering vomition and preventing the display of the only function which is apt to give any relief, and which nature itself has beneficently instituted as a *vis medicatrix*. This characteristic and uncomfortable condition is further aggravated by a total loss of appetite and an invincible repugnance to food in every form and shape—an inertia of the digestive organs, in fact, that is very rarely experienced in ordinary and even severe yet uncomplicated cases of seasickness. But the influence of the drug does not stop here; it reaches further yet and extends to the whole length of the alimentary tract, giving rise to great torpidity of the intestines; defecation becomes almost impossible without artificial measures, and is even then slow, difficult, and painful, and reacting unfavorably upon the entire system.

However favorably cocaine might affect the nervous system, intellect, and mind, under ordinary circumstances when taken on land, I have certainly failed to notice its brightening and inspiriting effects during the reign of seasickness, except that it sharpened the pangs of the latter by keeping the suffering victims wide awake and unable to find rest and oblivion in sleep.

The bromides have enjoyed a certain reputation in the treatment of seasickness since the late and lamented

Dr. Beard first recommended their use, and there can be no reasonable doubt of their partial efficacy in a large number of cases.

Of course, it would be an exaggeration to allege for them the potency of specifics or even uniform efficacy, but they exercise a palliative and sedative influence, and mitigate considerably the grave symptoms of the disorder. And yet, in the face of this admission, I should feel unwilling to recommend their use, as the unpleasant after-effects of the bromide treatment outweigh by far the benefits which it apparently confers. A great many persons who resort to the use of the bromides for the purpose of checking seasickness, and who saturate their systems with the salts almost to the extent of bromism, enjoy a certain kind of immunity while on the sea, only to discover afterward that they purchased comparative comfort at a very high cost. For, contrary to the usual rule of the disorder ceasing immediately after landing, they do not at once recover that bodily and mental equipoise that constitutes normal health, but suffer for some time with varied morbid sensations bearing a close resemblance to seasickness, and affecting alike body, mind, and temperament. This singular condition, which I experienced myself twice after using the bromides, and not otherwise, seems to be a direct and positive result of the medicinal agency employed, and of its physiological effort to overcome the affection. It appeared almost as if Nature had resented the check imposed upon her, and, in throwing it off, had reasserted her power and avenged the interference with her laws.

If I can thus adduce nothing in favor of cocaine and the bromides, it might not be amiss to say a good word in behalf of the hydrate of chloral, which renders excellent service in seasickness, without causing or leaving any ill effects. It does not directly interfere with and check the disorder, as the two other remedies seem to do, but merely mitigates and relieves the most distressing symptoms, and prepares the system gradually in overcoming the further inroads of the affection without much discomfort. It does not restrain the act of vomiting whenever this latter promises to afford relief, but it relieves the painful and convulsive heavings of the stomach, and, after being taken for some time, it finally stops the vomiting by removing altogether the nauseous feeling which gives rise to this gastric disturbance. The sensation of nausea being removed, vomiting ceases of its own accord. In doses of twenty grains, administered twice or three times in twenty-four hours, chloral relieves all the more prominent symptoms of the disorder, especially nausea, headache, nervous prostration, and mental wretchedness; imparts a sound and undisturbed sleep, which contributes as much, and perhaps more, to the general improvement than anything else; and keeps appetite, digestion, and action of the bowels in a pretty normal condition. Having crossed the Atlantic more than a dozen times, and experienced the horrors of seasickness in all degrees of intensity; having, furthermore, tried all modes of treatment, I can recommend but two measures—moderate doses of chloral whenever the remedy is not contra-indicated, and total abstinence from the use of excitants and stimulants in the shape of food and drink.

A bland, wholly unirritating diet is best tolerated by the stomach, and the effect of artificial appetizers is not only illusory but actually injurious, while the use of spirituous liquors considerably aggravates the gastric and cerebral symptoms. The reputation of champagne is exaggerated, and its good effects are solely due to the carbonic acid which it contains, and which proves far more beneficial in the simpler vehicle of certain mineral waters.

644 Lexington Avenue.

Book Notices.

Micro-organisms and Disease. An Introduction into the Study of Specific Micro-organisms. By E. Klein, M. D., F. R. S. Joint Lecturer on General Anatomy and Physiology in the Medical School of St. Bartholomew's Hospital, London. With 108 Engravings. London: Macmillan & Co., 1884. Pp. xii–195. [Price, $1.]

The reader will recognize in this book the series of articles which were published in the "Practitioner" for 1884. It is a modest little volume, but is none the less a thorough and scholarly exposition of the subject of which it treats. Dr. Klein's reputation as a bacteriologist, which has been increased by his prominent connection with the Cholera Commission, will render his book, small as it is, an authority upon the question of micro-organisms. He states briefly and clearly those facts which will be most useful to the general reader, avoiding scientific discussions so far as possible, and confining himself to concise statements of the latest theories. Of the twenty-one chapters, the first five treat of the methods of bacteria-cultivation and microscopical examination, the next three of bacteria and micrococci, while the ninth, tenth, and eleventh chapters deal with bacilli. Vibriones, spirobacteria, yeast and mold, fungi, and actinomyces, have each a separate chapter. Chapters XVII, XVIII, and XIX treat of the vital phenomena of micro-organisms. The concluding chapter contains a brief statement of our present knowledge with regard to germicides. The illustrations are well executed and assist materially in the understanding of the text. There are copious references to the literature of the subject, and a complete index. It is easy to believe from the amount of research displayed in the little work that it is the outcome of ten years of careful experiments and investigations, as is stated in the preface.

A Compend of Organic and Medical Chemistry, including Urinary Analysis and the Examination of Water and Food. By Henry Leffmann, M. D., D. D. S., Professor of Chemistry and Metallurgy in the Pennsylvania College of Dental Surgery, etc. Philadelphia: P. Blakiston, Son, & Co., 1884. Pp. viii–124. [Price, $1.]

As a quiz compend this handy little volume will be found to contain most of the information necessary to the medical student. The first half of the book treats briefly of organic chemistry. There are rather more ponderous formulæ than we should look for in such an elementary work. Animal chemistry receives a short notice. The section upon urine is the best in the book, being concise and practical. We are glad to meet with a full description of Dr. Squibb's simple quantitative test for urea. The picric-acid test for sugar is also not forgotten. A short chapter on water-analysis and one on foods conclude the compend. The book is neatly bound, and there is an exhaustive index.

NEW YORK, SATURDAY, OCTOBER 31, 1885.

DIELECTROLYSIS.

Among the "Therapeutical Notes" which we present this week, there is one that will undoubtedly awaken the interest, not to say the curiosity, of many of our readers. We refer to the brief paragraph which summarizes a communication lately made to the Paris *Académie de médecine* by M. Brondel, on the direct medication of the internal organs by what he terms "dielectrolysis," meaning thereby the electrolytic decomposition of a chemical compound and the forcing of its active medicinal constituent through the tissues of the body by virtue of its affinity for one of the poles of a galvanic battery.

Perhaps this is the most notable therapeutical novelty that has come up since the anæsthetic power of cocaine was announced. We think it proper to call it a novelty—just as we felt justified, some months ago, in speaking of rectal anæsthetization as a novelty, although something in the same direction had been done before by Pirogoff and others—although, within but a very few days of the date of M. Brondel's communication, a well-known French author, M. Spillmann, showed that, so long ago as in 1871, he had published something to the same purpose, and had referred to the idea as having been entertained by some others even at an earlier period. M. Spillmann's experiments were performed in 1870, and he published a note in the "Archives générales de médecine" (1871, vol. ii, p. 490), in which he said: "It is known that, by causing a galvanic current to pass through a solution of iodide of potassium, we cause the metal to be deposited at the negative pole, and the iodine at the positive pole. The same thing will take place if a tissue which is a good conductor is interposed between the two electrodes. It is easy to convince one's self of the truth of these statements. Beer ('Berl. med. Presse,' x, 1869, 37) and Eulenburg ('Berl. klin. Wochenschr.,' vii, 1870, 16) were the first to dream of the application of these phenomena. In my experiments I made use of glass cylinders, traversed at one end by a platinum wire, and closed at the other with an organic membrane. To avoid every source of error, the cylinders were scrupulously cleansed after every experiment, the membrane was changed, and the platinum wire was heated. Experiments were made by interposing a disc of potato, the thigh of a frog, a bit of veal two centimetres in thickness, then the forearm, the thigh, the hand, and the cheek."

M. Spillmann added, in substance: "It seems evident that iodine may be transported through living tissues from the negative to the positive pole. This transfer may take place even in cases where no reaction is found at the positive pole; in its transit through the tissues the iodine may encounter alkaline solutions by which it is arrested, and it may also be swept away in the circulation. If its therapeutical application is really efficacious, the method of which we have been speaking would have the advantage of acting directly and most intensely upon a given diseased part. I believe, nevertheless, that the application of electrolysis to the passage of medicinal substances is subject to many a drawback; the intensity of the current necessary to the purpose is generally such that often the patient can scarcely endure it. Moreover, can not the same results be arrived at, more slowly perhaps, by the internal administration of the drug?"

In something like the foregoing words, M. Spillmann calls up his former expressions in a recent letter to the "Gazette hebdomadaire de médecine et de chirurgie," and he adds: "These conclusions, which I formulated in 1871, I would to-day reproduce. Less fortunate than Dr. Brondel, I employed electrolysis for ganglionic tumors, goîtres, articular affections, etc., but, I must say, without much success. I also tried experiments with the aid of arsenical salts and salts of mercury. I did not think that I ought to persist in a course which seemed to me quite inferior to other well-known methods of introducing medicaments into the economy."

Certainly, we have here a valid claim of priority, but, alas, at the same time, a wet blanket thrown over the method. Another check to our enthusiasm is encountered in M. Dujardin-Beaumetz's report to the *Académie*, to the effect that M. Bardet, the well-known electrician, had repeated some of M. Brondel's experiments, and always with negative results. But it may be well to bear in mind M. Spillmann's suggestion as to the medicinal substance being arrested in its course through the tissues. At all events, it seems to us that M. Brondel's plan should not be hastily declared unworthy of further trial.

THE PROPOSED NATIONAL ACADEMY OF MEDICINE.

In this issue we publish a letter from the gentleman whose plan for a new national medical society we outlined some weeks since. Our correspondent now gives more definite details, and corrects some misapprehensions as to the precise scope of his idea.

There is only one point in regard to which we must utterly disagree with him, and that is his modest assumption that he himself is not likely ever to be made a member of such an august body as he proposes. He still wishes his name not to be mentioned in connection with the matter, and is even so careful as to ask not to have any hint given as to the locality from which he writes. While we accede to his preference in these particulars, we must express our regret that the weight of his name is withheld from the support of the undertaking.

We are quite convinced that some such plan as that which he has worked out will sooner or later be taken up by the profession. It is evident that such an organization would soon have weighty matters of business to act upon at its semi-annual meetings, but, yet, that it would be free from any temptation to such snap action as the American Medical Association took at its New Orleans meeting. It seems likely, therefore, that, not only as a scientific body, but also as the body most competent

to enact what little legislation the profession might be in need of from time to time, it would at once take the leading position before the world, regardless of what might or might not be done by the national medical associations now in existence.

MINOR PARAGRAPHS.

DIRECT MEDICATION OF THE SPINAL CORD.

The phenomena which Dr. Corning describes in this number of the "Journal," as the result of injecting a solution of cocaine into the tissue between two vertebral spinous processes, seem to point the way to a new development of the practice of local medication. The part which, as he suggests, may be taken by certain veins of considerable size situated in the interspinous spaces is a matter that is doubtless still to be worked out, but it will be seen that he lays little stress upon this matter of theory. The main point is that, should it be shown to be safe, the practice to which his observations may lead appears likely to offer a very prompt way of bringing a portion of the organism under the influence of a drug—one that may prove a precious resource in certain desperate conditions.

THE SUPPLY BILL AND THE STATE BOARD OF HEALTH.

While, as we pointed out last week, we can not admit that the Ways and Means Committee's interpolation of the word "deficiency" in the clause appropriating a sum of money to the board's use, to enable it to carry out a system of sanitary inspection, justified the Governor's veto—both because the context makes it apparent that the word was not intended to convey the idea that the board had asked for the means of making good a deficiency in the accounts, and because two other items for the board's benefit were likewise vetoed (one of them appropriating the small sum of five hundred dollars to cover various minor disbursements—among other things, for laboratory appliances)—we must, nevertheless, give it as our judgment that the committee was not at all warranted in submitting to the Governor a bill so loosely drawn. Surely, a "committee on style" would be in order at Albany.

AN ANTI-VACCINATION AGITATION.

Those unhappy individuals who from time to time make a public display of their horror at the practice of vaccination lately held a meeting in New York, at which they demonstrated anew their utter lack of appreciation of facts. There is little danger of their making any impression on the community; but why were they so cruel as to time their meeting so as to preclude the attendance of those of their brother "cranks" who may have felt more urgently impelled to take part in the meeting of believers in "faith cures" held in Buffalo?

INSANITY AMONG FEMALE PHYSICIANS.

"Lyon médical" makes the remarkable statement that statistics show the disastrous effects of medical study on the intellectual faculties of woman. In the year 1881, it appears from the census, there were twenty-five women practicing medicine in England, and our contemporary thinks that the number has undoubtedly increased since that time. From 1880 to 1884, eight had been placed in lunatic asylums, and at the close of last year three were under treatment.

NEWS ITEMS, ETC.

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, October 7th: *Montreal, Canada.*—For the week ending October 21st: The epidemic of small-pox has spread rapidly during the week. The deaths reported in the city were 394 and in the adjacent municipalities 96, as compared with 262 and 70, respectively, in the week ending October 13th; 2,454 deaths from the disease have been reported in Montreal and vicinity from the beginning of the epidemic to October 21st, inclusive. *Toronto, Ontario.*—For the week ending October 17th: No further reports of small-pox. *Havana, Cuba.*—For the week ending October 15th: 14 cases of yellow fever and 6 deaths. *Cardenas, Cuba.*—For the week ending October 17th: Free from epidemic diseases. *Matanzas, Cuba.*—For the week ending October 14th: The same. *Nassau, N. P.*—For the week ending October 3d: The same. *San Domingo.*—For the week ending September 16th: The same. *La Guayra, Venezuela.*—For the week ending October 3d: Yellow fever still prevalent and fatal in Caracas; a few cases of suspicious character have occurred in La Guayra. *Paris, France.*—For the week ending October 10th: 3 deaths from small-pox. *Rheims, France.*—For the week ending October 3d: 4 cases of small-pox and 1 death. *Antwerp, Belgium.*—For the week ending October 10th: 3 cases of small-pox. *Copenhagen, Denmark.*—For the month of August: 11 deaths from small-pox. *Barcelona, Spain.*—September 21st to 30th: 392 cases of cholera and 137 deaths. During the month of September 1,440 cases and 609 deaths were reported. The epidemic is abating generally, although an increase in the number of cases and deaths is observed at times, the victims being chiefly those who left the city on the appearance of the disease and have recently returned. *Cadiz, Spain.*—For the week ending October 3d: 73 deaths from cholera. *Valencia, Spain.*—For the week ending October 3d: 2 cases of cholera and 1 death. *Venice, Italy.*—For the week ending September 26th: 5 deaths from small-pox. *Trieste, Austria.*—For the week ending October 3d: 8 cases of small-pox and 4 deaths. *Prague, Bohemia.*—For the week ending October 8th: 2 deaths from small-pox. *Calcutta, India.*—For the week ending September 12th: 4 deaths from cholera. *Shanghai, China.*—August 21st to September 4th: 8 cases of cholera and 5 deaths. The disease is said to be more prevalent among the Chinese than for many years. *Toulon, France.*—September 5th to 10th: 57 cases of cholera and 23 deaths. The following is the number of cases and deaths from cholera in Italy from September 17th to 23d, inclusive: 1,323 cases and 820 deaths. In Spain, from March 4th to September 23d, there were 264,629 cases of cholera and 97,865 deaths.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending October 27, 1885:

DISEASES.	Week ending Oct. 20.		Week ending Oct. 27.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus	3	1	0	0
Typhoid fever	33	12	37	8
Scarlet fever	21	3	24	3
Cerebro-spinal meningitis	4	4	0	1
Measles	6	0	7	1
Diphtheria	53	22	46	25
Small-pox	1	1	1	0

The Cholera in Spain.—The United States consul at Santander reports to the Secretary of State, Washington, under date September 19th, that the epidemic is decreasing, and hopes are entertained that the disease will soon entirely disappear. The consul at Algiers telegraphs, October 24th, "public health is doubtful; ships will leave with foul bills of health."

Yellow Fever at Ship Island.—Three cases of yellow fever have been reported, at the office of the supervising Surgeon-General of the United States Marine-Hospital Service, as having arrived on a vessel recently from Havana.

The Medical Society of the County of New York.—At the meeting of October 26th officers were elected as follows: President, Dr. Daniel Lewis; Vice-President, Dr. Laurence Johnson; Secretary, Dr. Wesley M. Carpenter; Assistant Secretary, Dr. Charles H. Avery; Treasurer, Dr. Orlando B. Douglas; Censors, Dr. F. R. S. Drake, Dr. H. T. Peirce, Dr. W. E. Bullard, Dr. W. O. Moore, and Dr. F. M. Weld.

At the same meeting the following amendments to the by-laws were passed: The first one, offered by Dr. Jacobi and passed unanimously, reads "That the Comitia Minora be directed to recommend no applicant for admission to membership unless he be a graduate from a medical college in good standing, or a licentiate of a regular unsectarian State or county medical society of this or any other State; or, if his diploma or license be of sectarian character, unless the applicant declare in writing his or her abnegation of sectarian principles and practice." The second provided that the annual dues should be the sum voted at each annual meeting, but not exceeding five dollars. The third provided that the annual dues should be payable in advance after the annual meeting, and that they should be remitted, for the year in which they joined, to those who joined the society in the months of September and October. The first of the two following paragraphs was passed, by a small majority, after much discussion; the second was lost:

1. "If any member shall fail to pay the yearly dues within thirty days after the fourth Monday in November, when the same shall become payable, it shall be the duty of the treasurer to serve, in the manner in which notices in suits are required to be served on attorneys, upon each member so in default, a copy of this by-law and a notice to the effect that unless such dues are paid within fourteen days thereafter his name and the amount due by him will be reported to the society at its next succeeding stated meeting, and entered upon the minutes; and, if they are not so paid, the treasurer shall report the same accordingly. At the next stated meeting of the Comitia Minora after the date of such report, the Comitia may, by order, without further notice, strike from the roll the name of any member continuing in default, and he shall thereupon cease to be a member of the society, provided that, upon his written application explaining such default, and the payment of all dues to the date thereof, or provided that the Comitia unanimously remits the arrears, the Comitia shall have power to remit the penalty of this by-law."

2. "It shall be the duty of the treasurer to take a similar proceeding in the case of any member who shall have had credit for a part of his initiation fee, and also any candidate who has no credit for initiation fee, and who shall fail to pay the same after demand thereof made within fourteen days after the expiration of the three months allowed by the by-laws (Chapter XII, Article 4), for completion of membership; and the terms of the foregoing by-law shall apply to the last-mentioned cases in all respects."

The proposed amendment to Chapter IV, Article 4—which read, "It shall be the duty of the secretary to prepare annually, and send to each member of the society, a register containing the names, addresses, and office hours of the active members of the society, the register to be prepared at such time and in such manner as the Comitia Minora shall direct"—called forth remarks by Dr. Jacobi, who thought it would be better to provide for such a register by special action from year to year than in a by-law. It would be desirable, he added, if the society could prepare an official register for the entire State and adjoining counties, to take the place of the faulty register issued by the Medico-Historical Society. Dr. Loomis indorsed the remarks made by Dr. Jacobi regarding the desirability of having an impartial official register of the State and adjoining counties, and moved an amendment providing for the same to be issued by the county society. On motion, the whole matter was referred to the Comitia Minora with power. The annual dues for the coming year were fixed at three dollars.

The Discontinuance of the Michigan State Inspection of Travelers is announced in a circular, dated October 21st, addressed to the inspectors, and signed by the secretary of the State Board of Health, Dr. Henry B. Baker. The circular reads as follows:

"GENTLEMEN: The State Health-Inspection Service, established by this board under Act No. 230, Laws of Michigan, 1885, will cease immediately, in accordance with a letter this day received from Governor Alger, in which he says: 'Of course, however, the State Board will not discharge these officials until the [United States] Government takes the matter up.' By request of the Governor, I have informed Dr. H. W. Sawtelle, U. S. Marine-Hospital Service, Detroit, Mich., that 'this State will take no further action in the matter.' I understand that the reason for this is that the Governor considers that the 'Regulations for the Maintenance of Quarantine Inspections on the Northern Frontier of the United States,' issued by the Treasury Department of the United States (Department No. 153), and approved by the President of the United States, is applicable in Michigan as well as in other States, and that the United States Government should maintain the inspection in Michigan as well as in other States. In closing, permit me to thank you for your efficiency. During your service no small-pox has entered Michigan, so far as known; but it has been reported to have been conveyed from Montreal, by person or otherwise, to Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, New York, Pennsylvania, Illinois, and Wisconsin. The most exposed of any State, Michigan has so far escaped."

The rules under which the inspectors acted were as follows:

"1. All travelers and immigrants coming into Michigan from Ontario shall be subject to inspection by an officer appointed by the Michigan State Board of Health. 2. All baggage, household goods, and other effects, belonging to people moving into the United States or to suspected travelers, must be disinfected before entering the country. 3. All immigrants and suspected travelers who do not present proper evidence of recent vaccination or other immunity from small-pox must be vaccinated before entering the State. 4. After October 15, 1885, no passenger-car coming from Montreal or other infected district shall be allowed to enter the State without being properly disinfected. 5. Freight and cars from Montreal or other place liable to be infected, consigned to any place in Michigan, must be thoroughly disinfected before being allowed to proceed. (See Rules 19, 22, and 31, Rules of this Board, under Act No. 230, Laws of 1885.) Inspectors are expected to notify health officers of places outside of Michigan to which are consigned freight-cars from suspected places, if they are not disinfected because not consigned to this State."

The inspectors at Port Huron were Hiram R. Mills, M. D., M. Northup, M. D., and Mortimer Willson, M. D. Those at Detroit were J. J. Mulheron, M. D., Wm. Fitz-Hugh Edwards, M. D., F. W. Owen, M. D., A. B. Chapin, M. D., and F. D. Heisordt, M. D.

The Army Medical Corps.—We learn that a board is now sitting in New York for the examination of candidates for appointment on the medical staff. We have before published the circular usually issued to applicants, and we would now call the attention of candidates to the following paragraphs contained in the circular:

"III. Oral examinations on subjects of preliminary education, general literature, and general science. The board will satisfy itself by an actual examination that the candidate possesses a thorough knowledge of the branches taught in the common schools, especially of *English grammar, arithmetic, and history and geography of the United States.*

Any candidate *found deficient in these branches will not be examined further.*"

"IV. Written examination on anatomy, physiology, surgery, practice of medicine and general pathology, obstetrics, and diseases of women and children. Oral examination on these subjects, and also on medical jurisprudence, materia medica, therapeutics, pharmacy, toxicology, and hygiene. Few candidates pay the attention to hygiene which it deserves; it is always made a subject of this examination and will be considered *a vital one in the examination for promotion after the expiration of five years' service.*"

The Medical Society of the District of Columbia.—At a meeting held on Wednesday, the 28th inst., Dr. Joseph Taber Johnson reported a successful case of hysterectomy for tumor, the character of which will be determined by the microscopical committee of the society.

A New Medical College in Washington Territory.—The medical department of the Territorial University, at Seattle, was lately organized. The faculty consists of Dr. T. T. Minor (medicine), Dr. R. Willard (obstetrics and diseases of women and children), Dr. E. L. Smith (surgery), Mr. J. Baker (chemistry), Dr. G. A. Weed (physiology and hygiene), Dr. C. H. Merrick (materia medica and therapeutics), Dr. L. R. Dawson (anatomy and histology), Dr. J. W. Waughop (psychological medicine), Dr. J. C. Sundberg (ophthalmology, otology, and laryngology), and Dr. J. S. M. Smart (adjunct in clinical surgery and genito-urinary diseases).

The German Faculties.—According to the "Progrès médical," Dr. Werth succeeds Professor Litzmann in the chair of obstetrics at Kiel, and Dr. Ebner has been made a Privat-Docent at Prague.

Obituary Notes.—The death of Dr. Hewitt C. Fessenden, of Eastport, Me., took place on Thursday, October 22d, at the age of sixty-six. He was graduated from the Medical School of Maine, and had resided in Eastport for about thirty years.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 18 to October 24, 1885:*

McParlin, T. A., Colonel and Surgeon. Directed to await further orders in New York city. Letter from A. G. O., October 19, 1885.

Vollum, E. P., Lieutenant-Colonel and Surgeon. Assigned to duty as attending surgeon, Headquarters Department of the Platte, Omaha, Neb., relieving Assistant Surgeon William C. Shannon. S. O. 103, Department of the Platte, October 15, 1885.

Heger, Anthony, Major and Surgeon. Directed, in addition to his present duties as member of Army Medical Examining Board, now in session in New York city, to perform the duties of attending surgeon in that city. S. O. 240, A. G. O., October 19, 1885.

Baily, Joseph C., Major and Surgeon. Granted leave of absence for twenty days. S. O. 225, Department of the East, October 19, 1885.

Marine-Hospital Service.—*Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the two weeks ended October 24, 1885.*

Long, W. H., Surgeon. To proceed to Detroit, Mich., and assume charge of the service. October 23, 1885.

Austin, H. W., Surgeon. To proceed to Albany, N. Y., on special duty. October 14, 1885.

Williams, L. L., Assistant Surgeon. Relieved from duty at Norfolk, Va.; to proceed to Washington, D. C., for temporary duty. October 20, 1885.

Society Meetings for the Coming Week:

Monday, *November 2d:* New York Academy of Sciences (Section in Biology); Medico-Chirurgical Society of German Physicians; Morrisania Medical Society (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; St. Albans, Vt., Medical Association; Providence, R. I., Medical Association; Hartford, Conn., City Medical Association; Chicago Medical Society.

Tuesday, *November 3d:* New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo, N. Y., Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Hudson County, N. J., Medical Society; Androscoggin County, Me., Medical Association (Lewiston); Hampden, Mass., District Medical Society (Springfield).

Wednesday, *November 4th:* Medical Society of the County of Richmond, N. Y. (Stapleton); Penobscot County, Me., Medical Society (Bangor).

Thursday, *November 5th:* New York Academy of Medicine; Society of Physicians of the Village of Canandaigua, N. Y.; Medical Society of the County of Orleans, N. Y. (annual—Albion); Boston Medico-Psychological Association; Obstetrical Society of Philadelphia.

Friday, *November 6th:* Practitioners' Society of New York (private).

Saturday, *November 7th:* Clinical Society of the New York Post-Graduate Medical School and Hospital; Manhattan Medical and Surgical Society (private); Miller's River, Mass., Medical Society.

OBITUARY NOTES.

Professor Samuel G. Armor, of Brooklyn.—We regret exceedingly to be called upon to record the death of Dr. Armor, which took place on Tuesday, the 27th inst., in consequence, it is understood, of an attack of pneumonia.

Dr. Armor was born in Washington County, Pennsylvania, January 29, 1818. His parents, who were of Scotch-Irish stock, removed to Ohio when he was a mere child, and his training was therefore almost wholly in the West, Ohio being considered in those days a part of the far West. He took his medical degree in 1844, at the Missouri Medical College, in St. Louis. His attainments and his capability as a teacher were speedily and widely recognized, and for varying periods he was a member of the faculties of Iowa University, Cleveland University, the Medical College of Ohio, the Missouri Medical College, and the University of Michigan. Finally, in 1866, he was made professor of therapeutics, materia medica, and general pathology in the Long Island College Hospital, and the following year he became professor of the practice of medicine and of clinical medicine in the same institution, a position which he held up to the time of his death. He was also one of the visiting physicians to the hospital, a consulting physician to St. John's Hospital, and a member of the Medical Society of the County of Kings.

Dr. Armor was a painstaking and successful practitioner and an excellent lecturer. He often took part in the discussions at meetings of medical societies, and he usually preferred to write out his remarks for publication, rather than to trust to the reporters. The esteem in which he was held was not confined to the city in which he lived; far beyond the limits of Brooklyn he was recognized as one of the foremost of American physicians. He was possessed of a cordial, hearty manner which

won for him friends among all with whom he came in contact. His wiry physique gave promise of a long life, and the news of his death will therefore be all the more shocking to those who knew him.

Letters to the Editor.

THE PROPOSED NEW NATIONAL MEDICAL SOCIETY.

October 24, 1885.

To the Editor of the New York Medical Journal:

SIR: I am well satisfied to see by the Journal received today that my suggestion of last summer, relative to a National Academy of Medicine, has justified itself in the amount of attention it has attracted. It is particularly encouraging to be able to infer, from the variety of the views expressed by other journals and by your correspondents, that the main proposition—the present need of an authoritatively representative medical body in this country—is generally accepted and seriously considered by writers of widely differing opinions as to how the need is to be met. The project, if finally successful, must needs be such as is satisfactory to the profession at large, and can not be wisely formulated until every important criticism likely to be offered has been expressed and freely discussed.

When I offered you my suggestion I had in mind as an example the American Academy of Sciences. This body is, as you are aware, a close corporation, limited in number, whose membership is for life. Admission to its ranks is looked forward to by aspiring students of science as the crowning reward of their lives, and the visible and public evidence of their success. It is recognized by the national Government, to which it is the official and legal adviser as to all questions of scientific interest. It is not intended to, and does not in fact, occupy any part of the field of local or general scientific associations. And, although its annual elections rarely occur without causing bitterness and heart-burnings, often more or less just, because of its failure to choose men who have deserved the honor, this very fact is an evidence that its plan is successful in practice, since, if the honor were not earnestly desired, there would be little disappointment. And although, as has always been true likewise of the French Academy, any one can point to great names outside of the Academy with surprise that they are not upon its rolls, it is equally true that very few get in who ought to be out.

Very much such a body seems to me to be what is needed by the medical profession of the United States—not to take the place of the American Medical Association, or of any other geographically representative body which may hereafter be created, but to occupy a place of its own, the vacancy of which is just at this time sadly apparent to us all.

There is no scientific virtue in localities, nor can maturity of judgment or perfection of culture be mapped out by State lines. A true representation of the medical science of a country can only be expressed by the association of *representative men*—that is, of men who represent the high calling they have chosen, and not the particular section of the country in which they happen to reside. Who, for instance, would dare to maintain that such men as Austin Flint, Sr., or John C. Dalton, were representatives of New York city in any such broad and true sense as their names were household words in the mouth of every student of medicine in the whole extent of the country?

To limit the discussion, should it continue, to the proposition which I have in view, I will briefly restate it. I propose:

1. That there be organized a body of one hundred eminent medical practitioners, to be called the National Academy of Medicine.

2. That the Academy seek a charter from Congress, recognizing it as the official adviser of the Government, to which may be referred any question relating to preventive or practical medicine or the public health which may arise.

3. That membership in the Academy be for life, and that vacancies occurring therein be filled by the vote of its own members.

4. That its purposes be, *a*, the consideration of questions and prosecution of inquiries referred to it by the national Government; *b*, the discussion and investigation of questions and inquiries of general importance to medical science; *c*, the consideration of questions referred to it by local or general medical societies.

5. That its meetings be two in each year: the annual (business) meeting, to be held at Washington, D. C.; the semi-annual (scientific) meeting, to be held in such place, variable from year to year, as may be determined by vote of its members.

As to the best way of starting such an academy my inexperience is somewhat at fault, and you will need the counsel of wiser and more practiced heads. I will, however, suggest the following as preliminary steps:

Let an informal meeting be called of a very few of those best and most widely known as teachers in medical science and practice. You will not have to look far to find half a dozen names which are on the backs of well-thumbed text-books in every medical library in the United States. Let these gentlemen draw up a circular, stating the general purpose of their action, and send the same to a few of the most widely known medical men in every part of the country where truly representative men are to be found. Let the circular request the gentlemen to whom it is addressed to call meetings in their several localities to discuss the subject and to suggest modes of preliminary action—whether, for instance, delegates should be chosen (who should in no case be themselves candidates for membership) to a general meeting for the election of the first fifty of the Academy; or a plan for original representation should be drafted, apportioning membership in proportion to the number and standing of the medical schools in a district, according to which local elections should be held for the selection of the first fifty members. When fifty members shall have been chosen, let the Academy organize, and take its own deliberate time (the longer the better) for filling its number to the limit of one hundred.

The conditions for membership should not, in my opinion, be established until after the organization of the Academy; but I earnestly hope that the doors will be thrown open as widely as possible, exacting allegiance to no code or system, and excluding no class of so-called "specialists," in which material fit for the purposes of the Academy may be reasonably looked for.

Thus, although perhaps collecting its nucleus, for simplicity's sake, from districts bounded geographically, the Academy will be freed from local influences as soon as it is organized, and may fill up its ranks with due deliberation with those whom it regards as most worthy wherever it may find them.

The greatest difficulties seem to me to lie in the first formation of the Academy, and I am inclined to think that, considering the inborn bent of our countrymen toward political methods even in scientific matters, it will be well that as much as possible of the preliminary work be undertaken as a labor of love by those who, like your correspondent, have no hope of becoming members of the Academy themselves.

I am, sir,

THE CORRESPONDENT MENTIONED IN YOUR ISSUE OF SEPTEMBER 12TH.

THE CANADIAN EPIDEMIC AND THE STATE BOARD OF HEALTH.

Albany, October 14, 1885.

To the Editor of the New York Medical Journal:

Sir: I believe that few of the public or of the profession know either the limitations of the active powers of the State Board of Health, or the measures which it has been able to adopt to prevent the invasion of small-pox from Canada.

Although the board has nominally "cognizance of the interests of life and health throughout the State," and is verbally empowered to "from time to time engage suitable persons to render sanitary service," the very Act conferring these powers and duties stipulates that "no more than five thousand dollars in any one year shall be expended for such special sanitary service." Forasmuch as several acts were passed by the last Legislature calling on the State Board to supervise or prepare plans for public works involving special skill in sanitary engineering, the larger part of this limited sum is necessarily devoted to such purposes, and it has been beyond the power, though within the wish, of the board to engage competent inspectors at all the points of entry from Canada.

But, in partial compensation for this involuntary inefficiency of the central board, the new Public Health Act, passed last winter, makes it the duty of every local board of health

"To guard against the introduction of contagious and infectious disease by the exercise of proper and vigilant medical inspection and control of all persons and things arriving in such city, village, or town from infected places, or which, for any cause, are liable to communicate contagion; to require the isolation of all persons and things infected with or exposed to contagious or infectious diseases, and to provide suitable places for the reception of the same; to prohibit and prevent all intercourse and communication with or use of infected premises, places, and things; and to require and, if necessary, to provide the means for the thorough purification and cleansing of the same before general intercourse therewith, or use thereof, shall be allowed. And it shall be the duty of every such board of health to report to the State Board of Health promptly facts which relate to infectious and epidemic diseases, and every case of small-pox or varioloid occurring within its jurisdiction; and to provide at stated intervals a suitable supply of vaccine virus of a quality or from a source approved by the State Board of Health; and, during the existence of an actual epidemic of small-pox, said local board of health shall obtain fresh supplies of said virus at intervals not exceeding one week, and shall at all times provide thorough and safe vaccination for all persons within its jurisdiction who may need the same."

These measures are to be taken at the expense of the several localities, and, consequently, in a community of frugal-minded taxpayers, are not likely to be as thoroughly carried out as might be desired. To maintain a constant guard at places where trains are frequently arriving; to examine luggage and freight; to provide vaccine enough for all unprotected persons; to disinfect suspected articles; to provide a "quarantine of observation"—all these require an outlay of money, which, in a rural district, is reluctantly given. Nevertheless, to compel the execution of the act, it is decreed to be a misdemeanor on the part of any local board to violate "any lawful instruction of the State Board of Health."

Acting upon the authority thus given, as soon as small-pox was known to have assumed epidemic proportions in Montreal, early in June, a circular was sent to every local board of health on the frontier and along the main lines of travel, directing them to exercise watchfulness for the exclusion of infected persons or things, and to secure thorough vaccination, especially of school-children and persons employed about railway stations, boat landings, and other points of travel or traffic. Thanks to the energy of most of the local health officers, these precautions were promptly adopted, and in nearly all the exposed localities along our extensive border vaccination has been actively in progress, and the few cases which have been imported into the State have been effectively isolated without any spread of the disease. Continual correspondence, by circulars and letters, has been maintained with several hundred local boards, and every means short of pecuniary assistance that human effort could compass has been used to insure the protection of the State; with what success thus far is shown by the fact that, while small-pox was raging uncontrolled for months almost at our doors, not half a dozen cases crossed our line, and these had no extension. Now that the Canadian authorities are awakened to more decisive action, I feel even less anxiety than before popular apprehension was aroused, and greater confidence in the efficiency of the local boards which have already served their apprenticeship under the most disadvantageous circumstances.

The "epidemic fund" appropriated by Congress last year is under the control of the Treasury Department, and its financial aid is given, through the Marine-Hospital Service, only at the request of the Governors of States, addressed to the Secretary of the Treasury, boards of health having no direct voice in the matter. The Governor of New York has made official application for aid from this source, and means will ere long be provided for the inspection of trains before they reach the frontier; though even then the number of high-roads crossing our land boundary-line and the multitude of smaller places of debarkation along our lake and river shores will still be avenues of possible invasion which it would require almost an army to guard, and our chief reliance must be in the preventive efficacy of vaccination.

I am, sir, yours faithfully,

Alfred Ludlow Carroll, M. D.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of October 13, 1885.

The President, Dr. R. F. Weir, in the Chair.

Hæmatoma of the Thigh.—Dr. H. B. Sands presented a specimen obtained from the body of a man who died in June last in St. Luke's Hospital. The interest of the case lay in discovering, if possible, the seat of the lesion for which an operation was performed in the month of June, 1883. The case had been fully reported in the "Archives of Medicine" for December, 1884.

A man, fifty-one years of age, had suddenly developed in the left thigh a swelling of very large size. At first this was thought to be an aneurysm, but it lacked many of the features of an aneurysm, and Dr. Sands diagnosticated a hæmatoma communicating with a vein. At the time of the operation seven pints of blood, by measurement, were evacuated from the tumor, and it was estimated that a pint of blood was lost; in other words, the tumor contained a gallon of blood. He found a large opening leading from the sac into what seemed to be one of the profunda veins, and tied the vessel in question above and below the bleeding point. The man recovered and regained the use of his limb. Two years later he died in St. Luke's Hospital of visceral diseases implicating chiefly the liver and kidneys. At the autopsy a segment of the affected limb was removed and submitted for examination to Dr. Hall, who had made the following report:

About the middle third or fourth of the left femur, with an abnormally developed linea aspera, forming a sharp ridge where the perforating arteries pass through. Attached to the femur are a part of the vastus internus, and the adductores longus, brevis, and magnus. Left in position are part of the rectus femoris and sartorius, the superficial and deep femoral arteries and veins, the anterior crural nerve, and posteriorly the great sciatic nerve. Anteriorly the skin and superficial fascia have been stripped off in great part. At the inner side of the anterior surface of the specimen, above the vastus internus, a portion of integument has been left, containing a longitudinal cicatrix about three inches in length. The long saphenous vein has been dissected out and cut off above, but remains attached below. It contains a thrombus throughout its course. The fascia lata has been divided, and the muscles have been separated so as to expose the superficial femoral artery and vein throughout. They are pervious and apparently rather larger than usual, but not atheromatous. The profunda femoris is large and pervious down to the last perforating artery. Here the last perforating artery penetrates the adductor magnus and is continued pervious on the posterior surface of the specimen. The artery itself terminates close to the ridge of bone from the linea aspera in a mass of dense cicatricial tissue. An artery, apparently the continuation of this, emerges from the posterior surface of the specimen, from the cicatricial tissue, contains a thrombus, and is lost on the posterior surface of the adductor magnus. A single large vein accompanies the profunda artery, passes beneath the last perforating artery, and terminates abruptly in the cicatricial tissue. The cicatricial mass is about two inches in length, involves the attachment of the adductor magnus to the bone, and is connected with the cicatrix mentioned above. A large vein, not accompanying any artery, passes from below upward into the cicatricial tissue, and terminates in a small, irregular, almost obliterated cavity, partly filled with decolorized fibrin. It seems probable that a varicose vein accompanying a terminal branch of the profunda artery ruptured in or close to the attachment of the adductor magnus and gave rise to the hæmatoma, and that the terminal branch of the artery was ligatured during the operation.

Dr. Sands said that the specimen confirmed the opinion that the tumor was not aneurysmal, but was a venous tumor caused by rupture of a profunda vein, and it was possible that the determining cause of the rupture was the presence of a sharp ridge of bone springing from the femur. When the sac was emptied of clots, and before the tourniquet was applied, some fresh blood escaped, but, judging only from its color, he was unable to say positively whether it was venous or arterial; but the vessel in which the opening existed was of such large size that he had no doubt of its being a vein. The aneurysm-needle used was a rather sharp one, and in using it he punctured an artery, which, when the tourniquet was loosened, permitted hæmorrhage; but that point was at a considerable distance from the opening in the large vessel ligated. As the bleeding vein, owing to its deep situation and the condensation of the surrounding tissues, could not be isolated, the ligatures must have embraced the profunda artery as well as the vein. The blood also which flowed from the vein was very dark-colored.

A Contribution to the Ætiology of Malignant Tumors.—Dr. R. J. Hall read the following paper:

So much of an almost purely speculative character has been written during the last few years on the ætiology of malignant tumors that, did this paper contain merely a new hypothesis, I should scarcely venture to present it to the society. It consists, however, chiefly of a series of cases, most of which have come under my own observation, which, in my judgment, strongly support that hypothesis which is slowly but surely working its way into the minds of most thinking pathologists and surgeons. I refer to the hypothesis which attributes these mysterious neoplasms to a specific virus, in all probability a micro-organism.

Without stopping to give an accurate definition of the term tumor in general, it may be sufficient to say that by malignant tumors we mean such as invade the neighboring tissues and produce metastases (Ziegler, "Lehrb. d. allg. u. spec. path. Anat.," 2te Aufl., 1er Th., S. 214; Nidopel, Carc. u. Infl., "Med. Jahrb.," 1883, S. 123), and that all such tumors are included in two great classes, carcinoma and sarcoma. In regard to the first of these, almost all pathologists have accepted Waldeyer's view, that the cells which occupy the alveoli are epithelial, and the tumors therefore essentially of epithelial origin; while there is no doubt whatever that the sarcomata are built up of connective-tissue elements.

The theories hitherto formulated in regard to the origin of these tumors have been so well classified by Dr. H. F. Formad, in an exhaustive paper on the same subject (Ætiology of Tumors, "Trans. of the Path. Soc. of Phila.," Sept., 1879, to July, 1881), that I can not do better than reproduce his classification. Under each heading he has given a list of the pathologists who have supported the hypothesis. The list is as follows:

1. *Predisposition and Inflammation Theory.*—Virchow, S. D. Gross, Woodward, Samuel, Wagner, Birch-Hirschfeld, Cornil and Ranvier, Perls, Tyson, S. W. Fitz, Gross.

2. *Dyscrasia Theory.*—Rokitansky, Paget, Billroth, Simon.

3. *Embryonal Theory.*—Cohnheim, Thiersch, Waldeyer, Lücke, Masse, Hasse, Epstein.

4. *Idiopathic or Spontaneous Theory.*—Rindfleisch, Stricker, Nancrede, Payne.

5. *Nervous Theory.*—Van der Kolk, Lang, Snow.

The nervous theory is, I think I may safely say, too fanciful to merit discussion, except when considered as a possible predisposing cause. The idiopathic and dyscrasia theories mean nothing, the terms themselves being mere words which either confess our ignorance or serve as a cloak to hide it. Cohnheim's, or the embryonal theory, which has lately fallen into some discredit, undoubtedly offers a satisfactory explanation of the origin of some benign tumors, and may afford a beautiful explanation of one of the facts in regard to the structure of many malignant tumors apparently most difficult to reconcile with our hypothesis. For, if in certain regions, as the parotid, embryonic remains are of frequent or constant occurrence, and in others occur rarely or not at all, we can understand why in the one case the same irritant should give us a mixed, and in the other a simple tumor.

There remains, then, only the predisposition and inflammation theory. Under the great authority of Virchow, pathologists have been ready enough to accept this last as a sufficient explanation; that they have been, and are still, very slow to recognize that the inflammation is of a specific kind, is due, I think, chiefly to the following causes: When, following closely on his "Cellular Pathology," it was demonstrated by Virchow that tumors consisted of cells not differing genetically from those found in normal tissues, the discovery excited such enthusiasm that many were convinced that the life-history of the cell alone could sufficiently account for all the phenomena. Thus, according to the widely accepted view of Thiersch, in old age the resistance of the connective tissue is diminished, the interstitial spaces are widened; under some local irritation the deeper epithelial layers proliferate and penetrate the underlying tissues, enter the lymph-spaces, and are swept into the neighboring lymphatic glands, where, in accordance with their life-history, they develop indefinitely, and, not being on a surface where constant desquamation can occur, must do so at the expense of the surrounding tissues. Thiersch, while correctly recognizing the inflammatory character of at least one group of malignant tumors, the carcinomata, could not at that time make the distinction, now clearly recognized, between simple or non-infective inflammations and infective; and his followers, with less

excuse, refuse to do so even now. We have many instances of local infective inflammations giving rise to metastases—not one, so far as I know, of the non-infective. The view that malignant tumors are of inflammatory origin is one which has spread widely among pathologists, especially since it has been found necessary to place the so-called granulomata, tubercle, lepra, and syphilis among the inflammatory diseases. The points of analogy between these and the malignant tumors are too numerous and obvious to have escaped observation. They have been presented at length by Dr. Formad in an exhaustive paper, and by Dr. Nidopel. Time will only permit me to discuss them briefly to-night.

Tubercle, which may be taken as the representative of the granulomata, was long considered to be an ordinary inflammation in a tissue predisposed to disease; this is the standpoint which many pathologists occupy at present in regard to malignant disease. It is interesting to note Formad (The *Bacillus tuberculosis*, and some Anatomical Points which Suggest the Refutation of its Ætiological Relation with Tuberculosis, "Phila. Med. Times," Nov. 18, 1882), whose weakness for peculiarities in the lymphatic system as sufficient to account for the origin of tubercle led him to reject the tubercle bacillus, and brought down on him what can only be described as the annihilating criticisms of Professor Koch (Krit. Besprechung d. gegen d. Bedeutung der Tuberkelbacillen gerichteten Publicationen, "Dtsch. med. Wchnschr.," Nov. 10, 1883), and Dr. Shakespeare (A Criticism of Dr. Formad's Statements, etc., "N. Y. Med. Jour.," Aug. 16, 1884) finds, in the absence of the endothelium of the lymph-spaces, in carcinomata and sarcomata, a sufficient explanation of their peculiar growth.

Numerous attempts have been made to show that the anatomical peculiarities of tubercle tissue—epithelioid cells, giant cells, cheesy degeneration—are sufficient to account for all the peculiarities of the disease. The researches of Baumgarten ("Ztschr. f. klin. Med.," ix) and Weigert ("Dtsch. med. Wchnschr.," 1885, No. 35; quoted in "Med. News," Oct. 10, 1885) show that they represent only the reaction of the enfeebled cells under the irritation caused by the bacillus. A pathologist can hardly fail to be struck by the similarity of the enormously hypertrophied cells almost constantly found in sarcomata and carcinomata to the epithelioid and giant cells of tubercle, while the frequency with which they are found in a state of fatty degeneration and the readiness with which they undergo spontaneous necrosis remind us forcibly of cheesy degeneration. The discussion has not yet quite terminated among pathologists as to whether tubercle tissue always differs so much from other inflammatory products as to make the microscopic diagnosis possible in every case. In the same way the exact line between certain sarcomata and the products of chronic inflammation has never yet been drawn, while that form of tubercular skin disease known as lupus papillaris or verrucaseis, commonest on the dorsum of the hand, and of undoubted inflammatory origin, is, as I have myself had occasion to observe, indistinguishable under the microscope from epithelioma (Doutrelepont, "Ber. üb. d. Verhandl. d. dtsch. Ges. f. Chir.," 1885—Disk. üb. Tuberkulose, Volkmann). Into what absurdities we may be led by regarding carcinoma as merely a new specific inflammatory process is well shown by the statement of Formad (Ætiology of Tumors) that there are great numbers of chronic ulcers of the leg in the Philadelphia hospitals, and that a large proportion of them are carcinomata, because he has found epithelial nests and proliferation of the interpapillary epithelium. Both tuberculosis, as seen by the surgeon, and malignant tumors are distinctly associated with traumatisms. Thus, Volkmann states that the great majority of tubercular bone and joint diseases are referable to an injury (Erfahrungen üb. d. Tuberkulose, "Verh. d. dtsch. Gesellsch. f. Chir.," 1885), while Formad alleges that he finds an inflammatory origin in nearly one half of all tumors.

Dr. D. G. Zesas (Zur Kasuist. d. traumat. Tumoren, "Wien. med. Wchnschr.," 1883, No. 40; see also C. Mazzoni, Ueb. d. Sarkom., "Arch. di Med., Chir.," etc., vi, 40, f. 201, quoted in "Ctrlbl. f. Chir.," 1874, S. 169 [three cases of sarcoma after operation]; M. Landesberg, Zur Aetiol. u. Progn. intra- u. extraocularen Sarcoma, Virchow's "Arch.," lxiii, p. 1, 1875 [a case of sarcoma following an acute suppurative iridochoroiditis]; R. Barwell, On Acute Traumatic Malignancy, "Brit. Med. Jour.," Feb. 11, 1882 [gives several cases of sarcoma directly after injury]) quotes S. Wolff's statistics drawn from tumor cases observed in the surgical clinic at Berlin between 1864 and 1873, according to which, in 344 cases of carcinoma, a trauma was given as the cause 42 times, and in 100 of sarcoma 20 times.

It is well known that sarcomata usually follow a single injury, and carcinomata a long-continued irritation. The reverse is, however, by no means unknown. Thus, Weil (Sarcoma hæmorrhagicum, "Prag. Vierteljahresschr.," xxxiv, 4, 1877, p. 1, abstract in Schmidt's "Jahrb.," 185, S. 97) gives two cases of sarcoma attributed to repeated irritation.

Dr. R. F. Weir ("Am. Jour. of the Med. Sci.," April, 1876, p. 407) has reported a case of scirrhus of the penis following a contusion received four months previously, and refers to a similar case reported by Holmes Coote ("Med.-chir. Trans.," xlvii, 1863; see also Geber, Epithelialcarcinoma des Penis nach Coitus, "Wien. med. Presse," xii, 4, Jan., 1871, abstract in Schmidt's "Jahrb.," 160, p. 88). J. W. Hulke ("Med. Times and Gaz.," Feb. 8, 1873) reports a case, occurring in a man aged sixty-eight, in which a small wound of the palate, made by the stem of a pipe driven into the mouth, was followed in a month by a small "wart," which grew rapidly and, six months after extirpation, recurred, extended rapidly, and caused the death of the patient. Microscopic examination proved the tumor to be an epithelioma.

If we deny the existence of a specific virus in these cases, we are compelled to fall back upon the vague term predisposition, which was formerly used to explain the cases of tubercular disease having a similar origin. On the hypothesis of a non-specific inflammatory origin it would be difficult to account for the fact that in some countries malignant tumors are practically unknown (Formad, "Ætiology of Tumors"). For, surely, contusions and chronic inflammatoy processes, with diminished resisting power on the part of the connective tissue, can not be wholly wanting in these places. One of the strongest objections made to the assumption of a specific poison in the case of malignant diseases has been the absence of any evidence of contagion. Cohnheim ("Allg. Pathol.," 1877, quoted by Formad, *loc. cit.*) denied the existence of a specific poison, on the ground that the surgeon was never infected from the patient, *or the husband from the wife.* It is well to remember that precisely the same objection was made to the tubercular bacillus. Many physicians of large experience declared that they had never seen a case of even probable tubercular infection, yet now the journals are filled with them, and, while the surgeon seems still to be safe, the anatomist has not been spared (Cohnheim, *op. cit.*).

It is to meet this objection that I have ventured to present the following cases. Three of the series are from the practice of Dr. Sands, and one or both of the patients concerned in each case have come under my own observation; for the fourth I am indebted to Dr. Markoe, and the fifth was seen at the Outdoor Department of the Roosevelt Hospital by myself:

Case I.—Mr. Thomas E. C., aged forty, married, New York, clerk, admitted to Roosevelt Hospital December 3, 1878. Family history good. Patient has varicocele on the left side, and a tumor of the

left testicle, of twenty-two months' growth, of the size of a cocoanut, smooth, firm, and of fibrous consistence. Extirpation of the tumor, January 3, 1879, by Dr. Sands; death, January 26th, from suppression of urine due to pressure on the ureters by metastatic growths in the abdominal cavity. Microscopic examination by Dr. Delafield showed the tumor of the testicle and those in the abdominal cavity to be encephaloid carcinoma (Karg, Tuberkelbacilli in einem sog. Leichentuberkel, "Ctrlbl. f. Chir.," 1885, No. 32; G. Ricke, *ibid.*, 1885, No. 36).

Mr. C.'s widow, subsequently married, Margaret Anne, New York city, aged fifty years and three months, died, while under my care, April 12, 1885, with carcinoma "en cuirasse," originating in the mammæ. The tumors were stated to have been first noticed in 1882, and in both breasts at the same time. The growth was confined to the mammary glands and the skin; no enlargement of the axillary glands occurred, and only superficial ulceration of the carcinoma. Death was due to repeated hæmorrhages from the ulcerating surfaces and to exhaustion. No autopsy was obtained. Mrs. L.'s mother, Mary Anne D., died January 30, 1885, aged eighty-one years and six months, of acute bronchitis and broncho-pneumonia. One month before her death the patient consulted me with regard to a rapidly-growing tumor of the right breast which she had first noticed one month previously. My diagnosis was probable carcinoma. The tumor was seen also by Dr. Sands, who concurred with me. The family history of this patient was good. Especially there was no history of tumors. She had been a good deal with her daughter during the illness of the latter, but did not live in the same house. No autopsy was obtained.

Case II.—Mrs. D., aged forty-three, with a good family history, was subjected to operation by Dr. Sands, on May 3, 1882, for carcinoma of the right breast of one year's duration. Recurrence took place about six months later, and the patient died about April, 1883. Microscopic examination by Dr. Satterthwaite showed the tumor to be scirrhous carcinoma. Mr. George D., aged forty-seven, husband of the last patient, came under observation October 20, 1882, suffering from a tumor of the superior maxilla. A younger brother died five years ago of what was said to be recurrent sarcoma of the testicle. The family history was otherwise good. About three months ago the patient noticed a swelling in the left superior maxillary region, and thought he noticed a hard lump beneath the left angle of the lower jaw some time before this. Both tumors have grown rapidly since. A tumor of soft consistence occupies the situation of the left superior maxilla, and extends in the direction of the malar bone. There is a mass of enlarged glands beneath the left angle of the lower jaw. Extirpation of the tumor and enlarged glands was performed by Dr. Sands. Rapid recurrence took place, and death in May, 1883. Microscopic examination showed the tumor to be an epithelioma.

Case III.—Miss Isabella S. was admitted to Roosevelt Hospital, May 25, 1885, suffering from a rapidly growing tumor involving the right superior maxilla and said to be of three months' duration. Extirpation of the superior maxilla was done by Dr. Sands, May 27, 1885. Death occurred from shock and hæmorrhage following the operation. Microscopic examination showed the tumor to be a giant-celled sarcoma. Mr. F. J. G., aged twenty, single, was engaged to Miss S. for some months before her death. He was submitted to a surgical operation on September 9, 1885, by Dr. Post, for the removal of a small cystic tumor of the right superior maxilla, said to be of only three weeks' duration. The tumor lay in front of the antrum, and did not occupy its cavity. Microscopic examination showed it to be a giant-celled sarcoma.

Case IV (taken from Dr. Markoe's work on "Diseases of the Bones," New York, 1872).—Mrs. S. N. E., aged about twenty-three, consulted Dr. Markoe, March 26, 1866, for a small tumor occupying the right side of the neck, behind the sterno-mastoid, and of about the size of a hickory nut. An operation was performed May 1, 1866, when the tumor was found closely attached to the transverse process of the fourth cervical vertebra. Recurrence took place after a few months, followed by slow growth until April 10, 1869, when a second operation was performed. Recurrence took place in the autumn of 1869, with gradually increasing paralysis due to pressure on the spinal cord. A third operation was done January 25, 1871, followed by complete relief of all the symptoms, and there has been no recurrence up to the present time. Microscopic examination by Dr. Delafield showed the tumor to be a myxo-sarcoma. Mr. E., aged fifty-six, husband of the last patient, underwent, on January 19, 1885, an exploratory incision of the abdomen to determine the nature of an abdominal tumor, the symptoms of which dated from December, 1884. A soft, friable tumor was found matting the viscera together in such a way as to prevent the possibility of its removal. The tumor was considered by Dr. Markoe to be a sarcoma, probably originating in the great omentum. The patient died about three days after the operation. No autopsy was obtained.

Case V.—Thomas C., of New York, aged fifty-three, September 4, 1885. Family and personal history good. Especially there was no history of tumors or syphilis. Sixteen years ago he broke his left arm near the elbow, but recovered without stiffness or deformity. One month ago the left elbow and the right ankle became swollen, and the swelling has increased rapidly since, without pain, redness, or tenderness, except over the internal malleolus, where the pain is quite severe. Examination shows that the inferior extremities of the left humerus and the right tibia are expanded, so as to form distinct tumors of the lower ends of the bones, the tumors being smooth and of bony hardness. The neighboring bones and articulations are unaffected. A diagnosis was made of simultaneous sarcoma of the humerus and tibia. The patient was examined by a number of surgeons, who all concurred in the diagnosis. The tumors were especially unlike, in their growth and character, syphilitic or tubercular deposits, which almost alone might be supposed to come into consideration.

While taking the patient's history I incidentally elicited the fact that his wife had died last February, after a six-weeks' illness, with rapidly advancing hemiplegia of the left side, and that the diagnosis of the attending physician, Dr. A. R. Robinson, of this city, was tumor of the brain. Dr. Robinson, whose well-known skill as a pathologist lends weight to the diagnosis, informs me that the case was a well-marked one of rapidly growing tumor of the brain involving the motor areas about the fissure of Rolando, and, so far as the diagnosis could be made clinically, undoubtedly sarcoma. Syphilis especially was carefully excluded.

I am well aware that these cases are not beyond criticism, especially on the ground of the absence, in some of them, of a microscopic examination. This, however, was unavoidable, and in none of the cases, except possibly the last, could there be much real doubt as to the nature of the disease.

In Case IV the long interval which appeared to exist between the last appearance of the disease in the wife and its occurrence in the husband may seem to deprive the case of all significance. When we consider, however, the extremely slow growth of the original tumor, as seen in Mrs. E., and how long a similar one might exist in the abdominal cavity without giving rise to symptoms, the objection loses much of its weight. The length of time also that a tumor histologically malignant may remain latent, as contrasted with the frequently rapid growth of the same or similar tumors, is, I think, not sufficiently appreciated by pathologists, and offers another striking analogy to tubercular deposits. When a tumor which has remained quiescent for many years begins to grow and takes on the character of malignancy, surgeons are apt to assume that it has undergone a histological change from a benign to a malignant growth. The following cases tend to prove that at least sometimes the assumption is unwarrantable:

Case VI.—A small tumor, about half an inch in length by a quarter of an inch in width, adherent to the skin, but situated in the subcutaneous connective tissue, was removed by Dr. Markoe from the back of a healthy man, where it had existed for many years, with, I am informed, little or no change during that time. The tumor is a small-round-and-spindle-celled sarcoma, with little intercellular substance, and having histologically all the characters of malignancy.

Case VII.—Minnie M., aged eighteen, single, of good family history, noticed a tumor of the neck, below the lobe of the left ear, three years ago. The tumor is of about the size of a pigeon's egg, and resembles a conglomerate of enlarged lymphatics. She states that it has scarcely grown or altered since it was first noticed. Extirpation was done May

25, 1885. Microscopic examiñation shows it to be a myxo-sarcoma and histologically very malignant.

Case VIII.—Miss T. had a tumor in the same region, precisely similar to the former. She was a healthy woman, aged twenty-one. The tumor had existed for five or six years and grown almost imperceptibly. She desired operation only because a brother had died about one year previously of sarcoma of the pharynx. Extirpation was done by Dr. Sands January 23, 1884. Microscopic examination showed the tumor to be of almost exactly similar structure to the last.

The possibility of direct inoculation of the human subject or of animals with malignant disease has been much discussed, and many experiments have been made with generally negative or doubtful results. I have only been able to find in the literature of the subject two at all well authenticated cases of apparent inoculation. Meissner (Ueb. Krebs, Schmidt's "Jahrb.," 126, p. 121) states that, in 104 cases of melanotic sarcoma, one patient gave inoculation from a horse with the same disease as the cause. In the discussion on Dr. Formad's ("Ætiology of Tumors"; see also Kuhn, Note sur un cas de cancer médullaire transmis par inoculation d'un animal à l'homme, "Gaz. méd. de Paris," xvi, 1861, pp. 263, 391, 405) paper, Dr. S. W. Gross quoted from the "Mag. für die ges. Thierheilkunde," 1862, p. 328, the case of an ulcerating medullary sarcoma in an ox. A woman who cleaned the sore every day acquired a tumor of the outer side of the fourth finger of the left hand. Kuhn examined the tumor and found it to be a medullary sarcoma. Among cases of supposed contagion which can scarcely be accepted as evidence, Hynerth (De l'inoculation de cancer chez le lapin, "Gaz. des hôp.," 1873) refers to cases of contagion reported by Tulpius ("Nicolai Tulpii Amstelodamensis observationes medicæ," ed. nova, Amstelodami, CIↃIXLXXII: apud "Danielem Elsevirium observ. med.," Lib. iv, p. 292, 1672 [New York Hospital Library, No. 255]), and to those to which have been attributed the deaths of Smith and Bellinger. In a discussion by Dr. Mundé ("N. Y. Med. Jour.," Oct. 27, 1883) on cancer of the penis and contagion, the author states that Demarquay, in an analysis of 134 cases, found one where local contagion was alleged, and that Dr. Welch quotes Langenbeck as saying that he had seen three or four cases caused in the same way. Dr. T. Gaillard Thomas (abstract in "Med. Record," Nov. 7, 1883, p. 547) states that he has only met with one case of cancer of the penis in which contagion seemed to be probable.

There are a great number of unsuccessful or doubtful inoculations of animals, for an account of which I must refer to the general literature, and especially to Dr. Formad's article. The only experiments which seem beyond question are those of Professor Klincke (Häser's "Arch. f. d. ges. Med.," iv, 4, 1843, quoted in Schmidt's "Jahrb.," 126, S. 91), who inoculated a dog in the jugular vein and a horse in the conjunctiva with juice from a pigment carcinoma, taken from a mare. In the horse, in sixteen weeks the lachrymal gland was transformed into a melanotic tumor; the dog died in three months, and melanotic-tumor masses were found in the lungs.

Novinski (Zur Frage üb. d. Impfung d. krebsigen Geschwülste, "Ctrlbl. d. med. Wiss.," xiv, 1876, p. 790) made twenty-seven inoculations of carcinoma from the nose of a dog into inflamed tissue, and fifteen into normal skin. All of the first were negative; two of the last positive. In the successful experiment, a small piece of carcinoma (2 mm.) was introduced into a fresh wound of the skin of the back. The wound healed *per primam*. In fourteen days the fragment had reached the size of a pea, and in three months that of a walnut. Four months after the inoculation the dog was killed. The tumor measured 3·5 ctm. in diameter, and was soft and white in section. The lymphatic glands in the subclavicular region were much swollen. Microscopic examination of the tumor showed the peripheral part to be made up of closely lying polygonal cells, of epithelial character and varying in size, infiltrating the surrounding connective tissue. In the center there were alveoli of various sizes, with more or less fine tubercles and similar epithelial cells. The same structure occurred in the lymphatic glands. A young dog was then inoculated with a piece of this tumor, but died a fortnight later (of "*Pestkrankheit*"). Examination showed a small tumor at the point of inoculation: there were no metastases. The tumor showed a typical cancerous structure.

Dr. Gonjon ("Gaz. des hôp.," 1867, No. 85) gives two cases which do not appear quite so conclusive. He injected melanotic masses into the left thigh of a dog, and killed the animal after two weeks. At the point of injection there was found a melanotic tumor of the size of a Thaler; also pigment in the lymph-vessels and neighboring lymphatic glands. The lymphatic glands, including the bronchial, were enlarged and pigmented. The lungs were free. The same material was injected into the peritoneal cavity of a second dog, which was killed forty-three days later. At the point of injection and in the mesentery there were deposits of pigment. In one horn of the uterus there were two pigmented tumors. Few glands were affected; one inguinal gland was much enlarged. The bronchial glands were pigmented, but possibly this was from the lungs. All the pigment was in epithelial cells, but these were not similar to those of the tumor injected.

There is another way, however, of studying the subject. It will not be denied that there is not at present a pathologist of eminence who does not teach that malignant tumors are at first purely local. Could it be shown that sarcoma and carcinoma could be transmitted from man to man, or from man to animals, the idea that nothing but the cell was inoculated would not be able to hold its place in scientific opinion for six months. We have passed the stage when it was possible to believe that an infectious disease could be of spontaneous origin. Yet, if the disease is at first purely local, the inoculation of a distant portion of the body in the same patient, the so-called "contact-infection," is as valuable as the inoculation of another person would be. Cases of this kind are not rare in literature. The chief recorded instances are the following:

Dr. M. Nedopil (*loc. cit.*) quotes a case, narrated by Lücke, of ulcerated carcinoma of the edge of the tongue, with inoculation of the mucous membrane of the cheek on the same side; a case by Kaufmann, in which a woman had cancer of the dorsum of the right hand, and subsequently of the conjunctiva of the right eye; her relatives stated that she constantly wiped the right eye with the back of the right hand; cases by Ahlfeld (Beitrag zur Casuistik d. Uterussarkome, "Arch. f. Gynäk.," vii, 2, p. 301), Hegar (*ibid.*, ii), and Spiegelberg (*ibid.*, iv), of direct inoculation of the vagina from the uterus; and cases by Klebs of inoculation of cancer of the tongue, in the stomach. J. Reincke (Virchow's "Arch.," li, 3, p. 391) gives two cases in which carcinoma developed in the punctures made to relieve ascites due to carcinomatous peritonitis. Professor H. Quincke (Ueb. fetthaltige Transsudate, "Dtsch. Arch. f. klin. Med.," xvi, 2, p. 121) gives a similar case. C. Partsch ("Das Carcinoma," etc., Breslau), in giving statistics of carcinoma of the lips, penis, and vulva, relates one case of possible contact-infection. P. Kraske (Ueb. d. Entstehung secundären Krebsgeschwülste durch Impfung, "Ctrlbl. f. Chir.," 1884, No. 48) gives two cases of rectal carcinoma in which small secondary tumors were found at a lower point, separated by healthy mucous membrane from the primary growth, and refers to Virchow's well-known observation on the peculiar distribution of carcinoma of the peritonæum, secondary to carcinoma of the stomach (Virchow, "Die krankhaften Geschwülste," i, p. 54); to the cases of Lücke (Die Lehre von den Geschwülsten, etc., Billroth u. Pitha's

"Handbuch," ii, 1, S. 50), Kaufmann (Ueb. Multiplicität d. prim. Carcinoms, Virchow's "Arch.," lxxx, p. 347), and Klebs, mentioned above, and to a case by Erbse, in which a carcinoma of the œsophagus perforated the trachea and gave rise to secondary tumors in the lower lobes of the lungs.

Beck (Beiträge zur Geschwulstlehre, "Ztschr. f. Heilk.," v, 6, 1884, abstract in "Ctrlbl. f. Chir.," 1885, No. 34) records the following three cases from the Institute of Chiari, Prague. 1. Ulcerating cancer of the œsophagus. In the anterior part of the lower end of the œsophagus and in the stomach there was a tumor of the same character, flat-epithelial carcinoma. 2. Two carcinomata of the œsophagus separated by healthy tissue. The author admits the possibility of both being primary. 3. Multiple lymphadenoid round-celled sarcoma of most of the lymphatic glands, the lungs, spleen, and posterior surface of the stomach. In the ileum there were numerous similar nodules, not corresponding to Peyer's patches. In the cæcum there was an infiltration of almost the whole intestinal wall. The author excludes, on various grounds, all the other situations, and considers the growth in the cæcum as primary, and the other tumors in the intestinal tract as due to contact-infection, the tumor particles being carried back by antiperistalsis, the tumor of the cæcum being ulcerated and having caused much obstruction.

Beck quotes also a case, by Hjelt, of carcinoma of the ileum and colon, with primary cancer of the duodenum.

Two cases of the kind have come under my own observation, as follows:

Case IX.—Mr. A., an elderly gentleman, probably between fifty and sixty, suffered for several years from a slowly growing epithelioma of the floor of the mouth, on the left side, and encroaching on the posterior surface of the gums. Several operations were performed by Dr. Sands at varying intervals, with temporary success; but recurrence took place after periods varying from two or three years to several months. After the fourth operation, December 18, 1884, rapid recurrence took place. A flat epithelioma developed on the hard palate, just at the point where the tip of the tongue, constantly in contact with the epithelioma in the floor of the mouth, would frequently impinge. The diagnosis in this case was confirmed by repeated microscopic examinations.

Case X.—Mary M., aged forty-four, single, March 29, 1885. Family history good; no case of malignant disease known. Carcinoma of the right mamma, first noticed two years ago. Amputation of the breast was performed one year later. The axilla was not opened. Recurrence was noticed last October. Patient was first seen March 29, 1885, suffering from carcinoma, recurrent in the cicatrix of the operation, the new growth extending in the form of nodular masses, ulcerated in part, over almost the whole right side of thorax, anteriorly, laterally, and posteriorly to the external border of the scapula. The axillary glands on the same side were much enlarged, and the whole right upper extremity was enormously swollen, œdematous, and painful. On the left side of thorax, above the mamma, and on the left shoulder, were several isolated, non-ulcerated, cancerous nodules, varying in size from that of a split pea to three quarters of an inch in diameter, and not extending beneath the skin. There was a profuse sero-purulent discharge from the ulcers. The patient was last seen June 23, 1885, when the carcinoma had extended over the upper part of the abdomen and a great part of the right scapula and shoulder. Ulceration of the carcinomatous masses in the axilla had occurred. The discharge from the ulcers on the shoulder and in the axilla constantly ran down on the anterior and internal surfaces of the arm and forearm to the wrist, exciting an eczema and inducing the patient to scratch. *All along this surface there were cancerous nodules in the skin*, generally ulcerated, or excoriated on the surface; some isolated, others confluent, and extending to the wrist. She died of exhaustion July 10, 1885.

I may mention here one or two more interesting points of analogy between tubercle and malignant tumors. The former appears usually as a more or less chronic and localized disease. It occurs also as an acute infectious disease. Acute miliary tuberculosis involving the different organs with a rapidity that was a complete mystery to the pathologist until the views of Weigert (Ueb. Venentuberculose u. ihre Beziehung zur tuberc. Blutinfection, Virchow's "Arch.," lxxvii, p. 269, lxxxviii, p. 307; Neue Mittheil. üb. d. Pathol. d. acut. allg. Tuberculose, "Dtsch. med. Wchnschr.," 1884, No. 24), founded on careful anatomical research, were confirmed by the demonstration by Weichselbaum (Bacillen im Blute bei allg. acuter Miliartuberculose, "Wien. med. Wchnschr.," 1884, 12, 13), Baumgarten ("Ctrlbl. f. d. med. Wiss.," 1881, 15), and others, of tubercle bacilli in the blood. Raymond and Brodeur ("France méd.," 1883) record a case of primary acute miliary carcinosis, and refer to two similar cases by Charcot. Numerous cases have been reported, during the last few years, of general tuberculosis following operation on a local process, the operative interference having obviously opened the way for the bacilli into the general circulation (Koenig, "Bericht d. xiii. dtsch. chir. Congr."; also Tuberculose d. Knochen u. Gelenke, and Szuman, Brisement forcé eines scrophulösentzündeten Kniegelenks, etc., "Ctrlbl. f. Chir.," 1885, No. 29; P. Aubert, Le traitement du lupus à l'Antiquaille, "Ann. de dermat. et de syph.," iv, 3 [two cases of rapidly fatal phthisis pulmonum shortly after scarification of lupus]). A precisely similar general cancerous infection has been reported by Schweninger ("Bayer, ärztl. Intell.-Bl.," xxiii, 32) as follows: A girl, aged seventeen, underwent an operation for colloid carcinoma of both ovaries. The tumors were punctured shortly before the operation for diagnostic purposes. During the operation one of the tumors was torn. No reaction took place, and the wound practically healed in ten or eleven days. From this time there was a continued fever of remittent character, with diminished power and sensibility in the left arm and leg, and severe neuralgic pains and cramps in the affected extremities. Rapid extension of these symptoms took place to the right side, followed by bronchial catarrh, increasing weakness, and death, thirty-six days after the operation. A post-mortem examination showed that the peritonæum was thickly covered with carcinomatous nodules, varying in size from that of the head of a pin to that of a pea. Similar nodules were found in the liver, in the spleen, beneath the pleura, in the parenchyma of the lungs, and on the surface of the dura mater. In the interior of the brain there was a colloid tumor of about the size of a hen's egg.

Finally, it is with some hesitation that I state that I have found bacilli in a single case of rapidly growing, non-ulcerated, large-celled sarcoma of the occipital region occurring in a woman, and extirpated by Dr. Sands during the past year. The tumor tissue had been kept in ninety-five-per-cent. alcohol since the operation, and the sections were stained with fuchsin by a slight modification of de Giacomi's method for staining the bacillus of Lustgarten (Friedländer's "Fortschritte der Med.," 1885, 16, p. 543). The modification consisted merely in more prolonged immersion in the staining fluid, and may not have been essential. Every precaution was taken in the way of using sterilized vessels, reagents, etc. Of two sections examined, bacilli were found very sparingly in only one, and after prolonged examination. The examination was made with a Zeiss oil-immersion $\frac{1}{12}$, and Verick eye-piece No. 3, using, of course, the Abbé condenser. Though few in number, the bacilli found were very distinct, only one being situated in each cell, straight and apparently somewhat longer and plumper in proportion to their length than the tubercle bacilli. I know well, of course, that little or no scientific value attaches to a single observation of this kind by one man, unsupported by the evidence of any others, but mention it because it may acquire some if confirmed by future research; and at least it serves to

show that my work is not all theoretical, but practical as well. [The paper was followed by numerous references to literature.]

The President, referring to Cripps's latest work on "Diseases of the Rectum," stated that the author considered epithelioma of the rectum as probably parasitic in nature, which was supported by the fact that in the underground workers of certain mines in Silesia sarcoma occurred very frequently, whereas it did not prevail among those who lived in the adjacent country: and also that in the low lands near Liverpool in England there was no marked increase in the cases of cancer. The two cases quoted in the paper under the initial D. had been finally under his care, and they had struck him as bearing upon the question of contagion closer than any others he had ever encountered.

Dr. A. C. Post said that one interesting feature of the tumor upon which he had operated was that, although the morbid growth did not extend into the antrum, it had eroded its anterior wall so that he could pass his little finger into the cavity.

Dr. Sands was able to add another case to the list given by Dr. Hall—one in which malignant disease occurred in more than one member of the same family. A young man came to him three years ago on account of a swelling on the right side of the face over the spheno-maxillary and malar regions. It seemed to be due to the development of a tumor which was very deeply situated, and which, besides causing projection of the side of the face, was attended with a protrusion of the eye. He suspected the existence of a polypus of the spheno-maxillary fossa, and, with a view to remove it, he raised the malar bone, but was disappointed on discovering that, although a tumor was present in the spheno-maxillary fossa, it was not a polypus, but was firmly imbedded and could not be removed. The patient was known to be living, six months ago, in a state of great misery, the tumor having reached a very large size. About six months ago a brother of this patient was brought, in whom a tumor of large size had developed in the pharynx within a few months. It filled the pharyngeal cavity, and, although it was not firm in consistence, it was firmly attached. The disease was evidently malignant. The patient's general health had become very much impaired, and the speaker had been obliged to decline surgical interference. Probably both patients were now dead. They lived in the same house in Westchester County, and often occupied the same room.

It seemed to him that such cases, although they could not be accepted as proving the contagiousness of malignant tumor, indicated very clearly the direction in which future inquiries should be made in the hope of confirming the hypothesis of the parasitic nature of these morbid growths; for, certainly, there was no disease not already proved to be parasitic which would seem so likely as cancer to have such a mode of origin.

Dr. Hall remarked, with reference to the remarkable absence of cases of apparent contagion in literature, that it might be explained by the fact that, if the idea of specific poisons for malignant tumors was accepted, probably all cases recorded as of hereditary origin would fall under the head of infection. In tubercle practically the same thing was occurring now. Formerly all cases had been attributed to heredity, whereas now they were very largely attributed to infection. Congenital tuberculosis was extremely rare, and, while congenital carcinoma and sarcoma occurred, they were also extremely rare.

NEW YORK ACADEMY OF MEDICINE.

Meeting of October 15, 1885.

The President, Dr. A. Jacobi, in the Chair.

The Organization of the Section in Surgery was announced, Dr. Stephen Smith being Chairman, and Dr. A. B. Judson Secretary; the meetings to be held the second Monday of each month.

The Final Payment on the Property of the Academy was announced by Dr. F. A. Castle.

The Comparative Results of Operations in Bellevue Hospital.—Dr. Stephen Smith read a paper with this title, which was prefaced by this paragraph: "As we drift with current events we but imperfectly estimate the real advance which any art or science with which we are daily familiar has made within a limited period. It is only when we considerately pause and deliberately compare in detail past methods and results with those now practiced and obtained that we fully appreciate the vast changes which have so insidiously and imperceptibly taken place."

He then pictured Bellevue Hospital as it was in former years, located on the made lands of a cove of the East River, without drainage, adequate sewerage, or ventilation—a receptacle of typhus and typhoid fevers, small-pox, puerperal fever, cholera, and yellow fever. Bellevue Hospital had seen little of surgery before 1850; since then the increase of surgical practice in that institution had been gradual. The methods of procedure had been entirely revolutionized. Before the introduction of anæsthetics, the most important general principle governing the operator was celerity, whereas now, while the surgeon aimed to diminish the period of anæsthesia, mere haste was condemned. The surgeon's aim at present was to avoid suppuration. Formerly he troubled himself only to keep his instruments sharp, and paid little attention to cleanliness except as it guarded against rust. Now one of the assistants gave his whole attention to the instruments, placed them in a solution of carbolic acid, and took every means to render them clean. Formerly patients were brought directly to the operating-table without the part to be dressed or operated upon being even washed. Now the greatest pains were taken to clean the seat of the disease. Formerly the personal preparation of the surgeon and his assistants was only with a view to prevent soiling their clothing. No thought was given to the hands or nails. By-standers were invited to put their fingers into the wound without previous cleansing. The sponges were cleansed only in simple water; ligatures were carried in the surgeon's pocket; but one end of the ligature was cut off, the other being left for removal by traction after its final separation from the vessel. In closing an ordinary wound, the surgeon formerly took great pains to provide for the escape of pus, for he always expected suppuration. The final dressing was of adhesive plaster, and the bandage for support and retention. The plaster was never rendered aseptic, and, by its close relations to the wound, was dangerous. The bandage was usually of unbleached muslin, and added to the risks of infection. The surgeon left many wounds open which he would now close, for formerly he expected suppuration, while now he expected to avoid it. While describing the practice before the introduction of anæsthesia and antiseptics, Dr. Smith pointed out in contrast the methods of to-day. If we followed the wounds treated by former and by modern methods from the first to the last dressings, the contrast was remarkable. If the wound was large, on the second or third day the fever formerly began, announcing suppuration, and for weeks after the dressings were changed once, twice, or oftener daily. The pus-basin, irrigator, and dressing-forceps were in constant demand; there were fever, exhaustion, and depression of the patient, and then came chills, fever, and profuse sweatings, now called pyæmia, but then considered as only another stage of surgical fever. But metastatic abscesses were now things of the past. Everything was at present directed toward the prevention of suppuration.

The author then contrasted the treatment formerly adopted

in compound fractures, amputations, exsections, and ligations of arteries, with that now practiced. Amputations were not now thought of except where the nerves and arteries were so far destroyed as to prevent the conveyance of nourishment to the extremity. Formerly amputation wounds rarely, if ever, closed at Bellevue Hospital except after long-continued suppuration, and the larger ones were terribly fatal, whereas now they were among the most successful cases in the hospital, and death from suppuration and its results did not occur. Formerly psoas and other abscesses were allowed to go until they made an opening for themselves. Now they were opened and washed out with an antiseptic solution, often with the cessation of suppuration. Their walls being approximated after scraping, they frequently united almost at once. Septicæmia and pyæmia were now almost unknown in the gynæcological wards. Reviewing the surgical practice of Bellevue, it was not difficult to determine the essential feature of present methods as compared with those of the past; it was cleanliness. The agents now found efficient to secure this were soap and water to external parts, carbolic-acid solution for the instruments, bichloride solution to all surfaces and tissues, and iodoform for external dressings.

Dr. A. C. Post was prepared to accept the author's statements with regard to the thorough efficiency of cleanliness. He thought there was still room for doubt as to how far the use of antiseptics, so called, contributed to the success of operations other than as it secured cleanliness. His reason for doubting somewhat the part antiseptics played in contributing to the successful treatment of wounds was founded on the experience of the most eminent gynæcologists of Great Britain. Mr. Tait and Mr. Keith, the most successful ovariotomists, had regarded antiseptics, so called, as not only useless but pernicious; they maintained that the use of antiseptics added a small percentage of mortality to that class of operations. They both insisted, however, on thorough cleanliness. But there was no doubt of there having been a very great improvement in the treatment of surgical wounds, whether we regarded the improvement as due to antiseptic methods or to cleanliness.

Dr. W. Gill Wylie did not know whether we should have learned the full meaning of cleanliness had it not been that antiseptics, as introduced by Lister, had helped us to an understanding of it. He had no doubt that antiseptics had done good, but, like all things which had done good, they had been carried too far, and there was now somewhat of a reaction against them. He used antiseptics simply as a substitute for cleanliness, but if he could be sure of perfect cleanliness he would not use antiseptics.

Dr. Smith closed the discussion, and said that it had not been his intention to treat specially of the subject of antiseptics. Since the discussion had taken that direction, he might say, however, that in his opinion the value of antiseptics rested in their securing cleanliness. Extreme cleanliness now pervaded the wards of Bellevue Hospital. It was especially necessary that the surgeon's nails and hands should be rendered clean. Antiseptics had brought us to a knowledge of the necessity of cleanliness, and were adjuvants of cleanliness; so far as they assisted in securing cleanliness were they useful, and perhaps not much further than that. But those who were ridiculing antiseptics he thought were doing harm, for their followers might adopt less efficient methods of cleanliness than they did.

A Krackowizer Prize.—A communication looking to the establishment of a Krackowizer prize was referred to the Council with power. A resolution was also adopted authorizing the president to appoint a committee to take into consideration the advisability of certain changes of, or additions to, the constitution and by-laws.

NEW YORK CLINICAL SOCIETY.

Meeting of April 24, 1885.

The President, Dr. A. A. Smith, in the Chair;
Dr. Francis H. Markoe, Secretary.

The Treatment of Certain Fractures of the Bones of the Leg, and of the Patella, by Drilling and Wiring of the Fragments.—Dr. J. Williston Wright read a paper on this subject (see page 477), and showed several of the patients whose cases were mentioned in the paper. He also read the history of another case, prepared by Dr. Leroy W. Hubbard (see page 479).

Dr. V. P. Gibney commended the results. He was particularly astonished at the case of patella fracture shown. He thought that if simple fractures were oftener treated in this way there would be fewer cases which proved a disgrace to the profession—the increasing separation in time often rendering the limbs almost useless. He felt sure that with rigid antiseptic precautions there was little danger.

Dr. L. B. Bangs remarked that the paper had proved particularly interesting to him in view of a case which had lately come under his notice—one of compound fracture of the thigh in its upper third. The patient came under his care some days after the receipt of the injury, and when he saw it the fragments could not be replaced in position and the wounds were in a septic condition. He believed that, if the wire suture had been used early in this case, both the limb and the life of the patient might have been saved.

Dr. F. H. Markoe agreed with Dr. Gibney in believing that the unfortunate result which sometimes occurred after the most careful treatment of simple fractures of the patella might be averted by this method, but did not believe that in the present state of antiseptic surgery it should be adopted in all cases. It seemed to him that it must be particularly useful in cases in which there were well-marked obstacles to the putting of the fragments in apposition, as, for example, clots, etc., in which aspiration proved of no assistance.

Acute Phosphorus Poisoning.—Dr. E. G. Janeway reported a case as follows:

J. F. D., colored, aged twenty-five, United States, a waiter, was admitted to Ward 18 (Bellevue Hospital) April 9th, at 6 P. M. He was, from all external appearances, well, his pulse being full and regular, and his temperature in the mouth 98° F. He said he had taken, the evening before, ℥ j of bromide of potassium, having had a great deal of domestic trouble, and not having slept for a week. This gave him no sleep and produced no toxic symptoms. He confessed also that at eight o'clock the same evening he had taken the tops of three boxes of blue-topped matches, being influenced to do so by having read the account of a suicide by the same means. He was given an emulsion of magnesia and oil of turpentine, and his stomach was washed out with four quarts of water. He vomited out the tube and the remainder of the stomach contents, which smelled strongly of phosphorus, and in which were plainly seen the tops of matches.

April 10th, 8 A. M.—Temperature 99°, pulse 84 and irregular; complains of nothing but soreness in the back. During the night he had two diarrhœal movements.

10th, 12 M.—Temperature 98·75°, pulse 84, respiration 20; pulse intermittent. Was ordered whisky, ℥ ss. 3ia qu. h., and put on the use of liquid diet (milk and lime-water). 4 P. M.—Temperature 98°, pulse 90 and good. The urine was examined, and found of a reddish-yellow color, of acid reaction, and of a specific gravity of 1·030. It contained a trace of albumin, no casts, but amorphous urates. He had two scanty diarrhœal movements, containing little fæces.

11th, 4 P. M.—Temperature 99, pulse 72, respiration 25. Inhalations of oxygen-gas were ordered, of five minutes' duration, every half-hour during the day. He slept well during the night.

12th.—Complains of general weakness, and soreness in the back persists. The urine has been examined repeatedly, but no blood or casts have been found.

14th.—Doing well. The corneæ show slight jaundice.

16th.—Since the 11th inst. the temperature has ranged between 98° (morning) and 99° (evening). The pulse is good. He was allowed to get up, and the inhalations of oxygen were stopped.

He was discharged cured on the 20th.

The PRESIDENT remarked that for some years past he had taught the use of oxygen-gas in the treatment of acute phosphorus poisoning, but could not recall his authority for so teaching.

Dr. JANEWAY mentioned that, so far as he could ascertain, it was not recommended in any of the ordinary text-books.

Reports on the Progress of Medicine.

GYNÆCOLOGY.

BY ANDREW F. CURRIER, M. D.

Vicarious Menstruation and Menstrual Exanthemata.—Heitzmann ("Med. Jahrb.") remarks that by the term *vicarious menstruation* is meant the periodically recurring hæmorrhages from any portion of the body which recur at equal or nearly equal intervals of time, alone or in connection with menstruation. Such hæmorrhages may occur from mucous membranes (aside from the mucous membrane of the genital tract), or from or under the skin. Instances are related in which the bleeding has appertained to the bronchi, stomach, intestines, nasal mucous membrane, upper or lower extremities, cheeks, etc. In some cases pathological processes in different parts of the body have been associated with the phenomena. Within the last few years, especially since the publications of Leopold upon this subject in 1883, opinions have changed regarding the necessary interdependence of ovulation and menstruation. Many cases are on record in which menstruation has persisted after both ovaries were removed, and this with other facts compels us to look beyond the activity of the ovaries, or, at least, beyond the activity of the ovaries *solely*, for the cause of menstruation. The modern physiological explanation of normal menstruation is that it is an exudation of blood and blood-corpuscles, partly through the intact walls of the turgescent capillaries of the uterine mucous membrane, partly as a true hæmorrhage through the ruptured vessel walls which is favored by the construction of the mucous membrane and the falling off of its epithelial covering. The recent literature of this subject has been furnished by Leopold, Kundrat and Engelmann, Williams (J.), Wyder, Ruge (C.), and Möricke. The cause for the periodicity of menstruation has not yet been ascertained. The congestion which accompanies this function is not limited to the genital organs, and in this fact is a partial explanation of the occurrence of vicarious menstruation; at least it explains its possibility. Menstruation, whether it be normal or vicarious, is an evidence, too, of sexual maturity, and in this particular is to be distinguished from the hæmorrhages which occur before and after menstrual life, most of which, though they may proceed from the genital organs, are not connected with the monthly flow. The theory concerning the meaning and purpose of menstruation which seems most plausible to the author, though not entirely satisfactory, is that of Sigismund. This theory maintains that the uterus is prepared before the menstrual period for the presence and development of the ovum by the presence of the decidua. If the ovum is not fructified, there is no occasion for the nourishing function of the decidua, and it is cast off together with the ovum, menstruation thus being a kind of abortion. Now, regarding vicarious menstruation, in all the cases which were investigated by the author, abnormities or diseases were found in some portion of the genital tract as an explanation of the unusual hæmorrhage. Smallness of the uterus was especially noticed in this connection. Cases are quoted in which hæmorrhage occurred from the lungs, nose, stomach, nipples, scars, etc. As the time approached when the menses would naturally occur, hæmoptysis or hæmatemesis affected some of the individuals, while with others a swelling of some kind or other would be manifest, from which blood or bloody pus would be discharged for a few days, after which there would be a normal condition until the end of another month. Yet other cases are related in which with uteri of very small size there were scanty menstruation and a petechial eruption upon the skin. When the menses became normal the exanthem and other evidences of congestion disappeared, the *locus minoris resistentiæ* having been again established in its proper seat. From the cutaneous phenomena is deduced the natural inference that a reciprocal relation exists between the female genital organs and the skin, and the vicarious office of the latter is neither unwarranted nor infrequent. The performance of the same office by other parts of the body is, to a greater extent, exceptional.

Endometritis Dissecans.—Dr. P. Kubassow ("Ztschr. f. Geburtsh. u. Gynäk.," ix, 2) states, as the result of an analytical study of several preparations obtained during the past few years from patients with this disease, that the pathological process is an exfoliative inflammation of the inner layers of uterine tissue, involving not only a removal of the entire mucous membrane, but also of the contiguous bundles of muscular tissue. He finds in all literature only two cases recorded of a similar disease, and those were described by Siromjatnikoff, in the Russian language, in 1880. In one of his cases the patient died, and the uterus was carefully studied. The result was confirmatory of his opinions concerning the nature of the disease, and showed that the exfoliations were not a product of abortion or of membranous dysmenorrhœa. In each case the exfoliation occurred at or near the menstrual period. The part which was thrown off was three-cornered, had three openings, and included mucous membrane and uterine muscular tissue. With it there was also a discharge of blood, pus, and mucus. The patients showed some elevation of temperature at the time, which dropped to normal and was followed by recovery in two of the cases; in the third it became sub-normal and was followed by death. The process which resulted in this loss of substance was partly phlegmonous and partly hæmorrhagic. The study of these specimens has convinced the author that the disease is not so rare as might be supposed. The difficulty in obtaining the discharges of women will prevent such an investigation of the subject as would be desirable. Turning again to the process by which the exfoliation is accomplished, the author remarks its similarity to the process which often obtains in scurvy. Severe hæmorrhages during the process are not likely to occur, on account of the thrombi which, evidently, are quickly formed in the divided vessels. The mucous membrane may be regenerated from the small islands of that tissue which are left when the main portion is swept away. The causes of this affection are both predisposing and constitutional, but our imperfect knowledge of the subject prevents greater definiteness. The symptoms noted, in addition to rise of temperature, were vomiting, diarrhœa, dysuria, lessening of the heart's activity, acceleration of the respiration, etc., and also others which were directly referable to the pelvic organs, bearing-down pains, pains in the sides, and the mixed discharge alluded to. The prognosis can not always be favorable, especially if the Fallopian tubes are involved. Such a complication proved fatal in the third of the author's cases. In the way of treatment, the general health must be brought to as high a standard as possible, and locally such means must be used as are helpful in relieving uterine congestion [which the author seems to consider the principal element, or one of the principal elements, of disturbance]. Chief of these is the abstraction of blood by scarification or leeching. Narcotics and poultices will be required should the pain be severe.

The Significance of Alterations in the Kidney which follow the Development of Fibroid Tumors of the Uterus, with reference to the Indications for and the Prognosis of Hysterotomy.—Pozzi ("Ann. de gyn.") summarizes his paper in the following conclusions. 1. Compression of the bladder and the ureters is a complication which is frequent with fibroid tumors of the uterus, even with those which are moderate in size. It may involve, and with rapid progress, grave altera-

tions in the kidneys, such as hydronephrosis, cysts, sclerosis, and fatty degeneration. 2. When this compression is exerted upon the bladder its effect is readily recognized, but the same is not true when the ureters are encroached upon, and a positive lesion can not always be diagnosticated until albuminuria has supervened. 3. Compression of the bladder or ureters ought to have great weight among the indications for operation, and may, of itself, determine active interference on the part of the surgeon. 4. When hydronephrosis exists, the indication for operation is an urgent one, especially in view of the danger which threatens the unaffected (or presumably unaffected) kidney. In cases of this character hysterotomy should first be performed, and when the patient has recovered from that operation the cyst may be attacked. 5. The prognosis of hysterotomy is grave, according as the analysis of the urine indicates renal disturbance. If Bright's disease is clearly established it would be a positive contra-indication to the operation, but a slight degree of albuminuria would not be a contra-indication.

The Statistics of Uterine Cancer and its Operative Treatment.—Hofmeier ("Ztschr. f. Geburtsh. u. Gynäk.") states that a new era in the operative treatment of uterine cancer began with the announcement of Freund's operation. Ruge and Veit have studied and published the account of the pathological anatomy pertaining to the subject. The question recurs continually, Have the results which have been obtained repaid the time and labor which have been expended. The statistics of this paper were gathered mainly from the records of Schröder's policlinic and his private practice. From the former, of 18,000 cases, 603 were cases of uterine cancer. From the latter, of 9,400 cases, 209 were of uteriue cancer, respectivcly 3·6 per cent. and 2·18 per cent. The great preponderance of cases in publie over those in private practice is uoteworthy, and is attributed by Schröder to the severer experience of the poorer classes in the struggle for existence. The age of the patients in the collated cases varied between 20 and 85, no cases being presented under 20:

From	20	to	29	years of age	there were	16 cases.
"	30	to	39	"	"	195 "
"	40	to	49	"	"	272 "
"	50	to	59	"	"	192 "
"	60	to	69	"	"	65 "
"	70	to	79	"	"	7 "
"	80	to	85	"	there was	1 case.

In only 39 of these cases were the patients nulliparous, and the rule was, as has been enunciated by Gusserow, the greater the number of children, the greater the predisposition to cancer. Of the individuals referred to in the foregoing table, 76 had borne 10 or more children each. It was observed that the puerperal period is especially favorable to the rapid development of the disease. Of the entire number of cases studied, in 236 there was cancer of the (1) portio vaginalis, in 181 it affected the (2) cervix [*i. e.*, the supra-vaginal portion of it], in 28 the (3) body was involved, and in the remaining 367 the variety is not specified. The average age of those who are included in the first variety was 42, of those in the second 47, of those in the third 54·5. The average number of children borne by those who are included in the first variety was 6; 7 of them were nulliparæ, 33 were primiparæ. The age of the youngest in this group was 26, that of the oldest was 63. In the second variety the average number of children was 6·5; in 4 of the cases the patients were nulliparous, in 23 they were primiparous. The disease in this (2) variety came late in life, in many cases, frequently long after the menopause. Of the third variety 21 per cent. were nulliparous; the average number of children was 3·6. No individual was operated upon until after a thorough examination under anæsthesia had been made, and no hope of permanent recovery was held out in cases in which the uterus was fixed, or the folds of Douglas's *cul-de-sac* and the tissue surrounding the cervix were involved. The magnitude of the operation (*i. e.*, whether complete or partial extirpation) was limited mainly by the variety of the disease. In 160 cases operatious were performed in the hope of obtaining a radical cure. The prognosis of ultimate recovery was least hopeful in those cases in which the cervical mucous membrane was affected, since the probabilities were strongly in favor of the disease being extensively diffused at the same time. This was especially true in old women. In 96 of the cases in which the portio vaginalis was involved, vaginal or supra-vaginal amputation was performed; in 8 the uterus was extirpated *in toto*, *per vaginam*. Of the 39 cases of cancer of the cervix (supra-vaginal, or cervical mucous membrane), in 9 supra-vaginal amputation was performed, and in 30 the entire uterus was removed, 6 of the latter operations being by Freund's method. In 17 instances operations were performed for cancer or sarcoma of the body of the uterus, 13 of them consisting in the abdominal supra-vaginal amputation, and 4 in total extirpation of the uterus; two of the latter operations were after Freund's method. Of the 160 cases operated upon, 31, or 19 per cent., were fatal—20 from septic infectious processes, within a few days, 8 from hæmorrhage, in most cases within a few hours after operation, 1 from trismus, 1 from shock after Freund's operation, and 1 from iodoform poisoning. Of the vaginal and supra-vaginal (cervical) amputations 12·3 per cent. resulted fatally. Of the vaginal and supra-vaginal (by abdominal section) total extirpatious 26 per cent. of the former and 30 per cent. of the latter resulted fatally. Of the Freund operations 62 per cent. were fatal. Of the 17 cases of cancer of the body of the uterus in which operations were performed, 6 were fatal from the immediate effects of the operation, in 4 the ultimate result was not ascertained, in 3 others a fatal issue from recurrence of the disease occurred within a year, and in the remaining 4 there had been no recurrence during periods ranging from two to five years. In the 19 cases of total extirpation the operation was too recent for any judgment as to its ultimate value in 2 of them, in 5 the disease recurred within six months, in the remaining 12 only 2 were quite free from recurrence after three years. In 7 cases of cancer of the cervical mucous membraue the supra-vaginal amputation (*per vaginam*) was performed, and only two of the patients were free from recurrent disease at the end of two years. Iu 96 cases of cancer of the portio vaginalis, vaginal or supra-vaginal amputation was performed, 85 of the patients surviving the operation. At the end of three years 12 of these 85 were known to be entirely well; concerning several no report was obtainable; all the others had suffered recurreuce. The uterus was entirely removed *per vaginam* in 8 instances for disease of the portio vaginalis, 7 of the patients recovering. At the end of fourteen months only 1 of the 7 was known to be well. Of 129 successful operations of all kinds, there had been no recurrence after two years in 28 cases—that is, 21·8 per cent. In four of these, however, the disease recurred at periods varying from two years and a half to three years aud a half. Notwithstandiug these unfavorable facts, the author believes that an extension of life for two years is ample justification for the risks of a capital operation. The most favorable prospects for radical cure are thought to be offered by an operation which shall consist of excision plus the use of the actual cautery. In comparison with this method of operation Schröder does not think favorably of the galvano-cautery wire. As a summary, the results which have been set forth by these statistics, though not so favorable as could be desired, furnish a justification, in the opinion of the author, for a continuance of operative measures.

Nephritis consecutive to Epithelioma of the Uterus.—Lancereaux (" Annales des mal. des organes gén.-uriu.") boldly advances the proposition, which he thinks is justified by his experience, that in every case of epithelioma of the neck of the uterus there is, at some time, nephritis existing as a complication. This lesion is distinct from primitive interstitial nephritis, and is not, like that, accompanied by hypertrophy of the heart. Twenty-three cases are detailed to substantiate his proposition, these being cases which could be thoroughly investigated post mortem. Three varieties of epithelioma may affect the uterus, or, in other words, as many varieties as there are varieties of epithelium in connectiou with the uterus. That which is developed from pavement epithelium is the most common form, and may begin either from the vaginal *cul-de-sac* or from the lips of the vaginal portiou of the cervix. It is this variety also which, on account of its situation, predisposes more than any other to degenerative chauges in the urinary passages and the kidneys, and it is the sole variety to which the author refers in this paper. Its progress is marked by ulceration, with its accompanying fœtid, sanious discharge, and by the characteristic indurated condition of the tissue of the *vaginal portion* of the cervix. The hæmorrhages which accompany its development are, in some cases, so severe as to lead to a fatal issue before the kidneys have become involved,

such cases being, of course, exceptions to those which are laid down in the author's general proposition. Notable features of the disease, also, are severe pain, especially along the course of the lumbar and sciatic nerves, disordered digestion and nutrition, and various troubles in connection with the urinary passages. Urination becomes frequent and painful, and may be accompanied or followed by spasms. The urine may be bloody, and under the microscope may reveal epithelial cells, leucocytes, and crystals of various kinds. At other times it may be clear, pale, and abundant. In still other cases it may be purulent. Its solid constituents are very apt to be diminished. In the larger portion of the author's cases albuminuria was present, and uræmia, more or less intense, was so common that it was regarded as the rule. The form was that which affects the alimentary canal, being manifested by loss of appetite, vomiting, and diarrhœa. Less frequently uræmia, with cerebral manifestations, was present, being manifested by headache, insomnia, delirium, or coma. Uræmia accompanied by dyspnœa was rarely seen. Uræmia, in some form or other, is assumed to be, habitually, the cause of death, if that event is not attributable to some accident, or to a complication. The propagation of this disease seems to be, in the majority of cases, in the direction of the bladder rather than that of the rectum. It is brought about by means of the epithelial traces which lead to the formation of an embryonal connective tissue in the midst of the tissue which unites the bladder with the upper part of the vagina and the cervix uteri. Next epithelial elements appear in this tissue, which, as they develop, compress and produce atrophy of the muscular fasciculi, and form nodosities which project toward the *bas fond* of the bladder and along the course of the ureters. The resulting ulceration leads to vesico-vaginal fistula. The ureters, surrounded by the epithelial growth, become nearly occluded at the point of obstruction. Above that point they become dilated by the retained urine, as well as the pelves and calices of the kidneys, the Malpighian bodies become atrophied to a greater or less extent—in a word, there is a condition of hydronephrosis. After a primary enlargement of the kidneys there follows a diminution in size. The capsule may be easily removed, revealing the free surface of the organ smooth, yellowish, and without granulations. The cortical substance is thin, firm, and yellowish upon section. The pyramids are small, indurated, and sometimes atrophied. Microscopical examination shows that the lesion of the kidney, in cases of this character, is a diffuse sclerosis, and, in the author's experience, it was most pronounced at the summit of the Malpighian bodies, the uriniferous tubes being here separated by bands of embryonal tissue and the tubes themselves being more or less atrophied. At the middle and base of the Malpighian bodies the process was found to be less intense. The cortical substance is involved in this process, the glomeruli and the convoluted tubules of the periphery being chiefly implicated. In many of the tubules the epithelium has disappeared, in others it is only disarranged. These are the principal characteristics of nephritis which is consecutive to uterine epithelioma. The disorders which follow the imperfect performance of its functions by the kidney are principally those which have reference to the alimentary canal.

On the Treatment of Uterine Cancer; Advantages of Amputation of the Neck of the Womb with the Galvanic Wire.—Gallard ("Ann. de gyn.") urges the propriety of giving more attention to what are apparently hopeless cases of disease, referring especially to uterine cancer. He has tried the plan of injecting, with caustic fluids, diseased tissues and those which are immediately contiguous to them in the hope of staying the progress of the disease, but no lasting benefit has resulted; indeed, he thinks such measures are oftener harmful than useful. Cauterization with iron at red heat has given good results in a certain number of cases, but it is believed that the simple burning of the diseased foci is not sufficiently radical in such a disease as cancer of the uterus. The serre-nœud of Maisonneuve and the écraseur furnish more thorough means for operation than any of the foregoing, but they have certain disadvantages, among which may be mentioned difficulty of adjustment and liability of the wire either to slip or break. With the galvanic wire adjustment is easier, for only a fine wire is required, and this can be guided by the fingers to the desired point, and kept in position during the operation without much trouble. The electric current having been established, the cervix, grasped with hook-forceps, is to be drawn slowly downward until the uterine tissue is cut through. The author does not deny that the same accidents may occur with the cautery-loop which frequently happen with the serre-nœud or the écraseur, and in some cases it has been necessary to abandon the use of the former and complete the operation with one of the latter instruments. Twenty-five cases have been operated upon by the author, in which more or less complete histories have been taken. Twelve of these have, it is thought, been cured. In three of them the time which has elapsed since the operation is, respectively, eighteen months, two and a half years, and nearly four years, and no trace of the disease is discoverable. Even should the disease return after the operation with the galvanic loop, its progress seems to be less rapid than when a cutting instrument has been used, probably because of some modification which the tissues have undergone as the result of the operation. Accidents following the operation are very rare, occasional hæmorrhages having been observed. There is some pain, but not so severe as in some classes of burns, and it may readily be relieved. The patient should remain in bed for about three weeks, during which time there should be no examination or treatment, unless it is imperatively demanded.

Total Extirpation of the Uterus by the Vagina.—Demous ("Rev. de chirurgie") remarks that extirpation of the uterus is one of the operations which have been considered unjustifiable by many surgeons, and that there are some who so consider it even at the present time. Of ancient origin, it was for a long time discarded, to be revived, like many others, as the fruit of antiseptic surgery. Especially in cases of cancer of the uterus does it hold out the single chance of relief from that dreaded and dreadful disease, but it is also worthy of consideration in any chronic disease of the uterus (1) when that disease threatens the patient's life; (2) if there is a certainty that no other operation holds out any chance of recovery; (3) if complete removal of the diseased parts can be accomplished without wounding neighboring organs; (4) if no other fatal disease complicates and contra-indicates the operation. A large, rigid, and unyielding uterus and a small vagina would be effectual contra-indications to the performance of the operation. When operation has been decided upon, in a given case, the following plan of treatment is suggested by the author as appropriate: Rest for a number of days preceding the operation, especially if the patient is subject to hæmorrhages; hot vaginal injections of carbolized water, during the same period, frequently repeated; a cathartic on the evening of the day preceding the operation, and a rectal injection the following morning. The operation should be performed in a well-lighted and ventilated room, with an even and mild temperature. After the patient has been placed in the lithotomy position, the hair should be shaved from the genitals; the vagina, vulva, and contiguous parts should be disinfected with carbolized water of the strength of 30 to 1,000. The bladder should be evacuated, and, at one's option, an application of chloride of zinc may be applied to the cervix. The last-mentioned recommendation is both for purposes of antisepsis and to diminish the probabilities of hæmorrhage. Next, the walls of the vagina are separated widely with retractors, the cervix is seized with a volsella and drawn downward and forward as far as possible, and a circular incision of the vagina is made with a straight bistoury at a sufficient distance from the uterus to include healthy tissue, if that is possible. The further separation of the cervix from its surrounding tissues should be made by tearing with the finger, if the tissue is not so firm that a cutting instrument is required. The close proximity of the bladder, and the danger of wounding it, must be borne in mind, as the dissection is continued until the anterior peritoneal *cul-de-sac* is opened. This opening must be extended until the uterus is freed from its attachments anteriorly, after which the organ is to be completely retroverted, either by the fingers passed into the anterior opening, or by instrumental means. The most difficult part of the operation follows, namely, the ligation and division of the broad ligaments. Catgut ligatures are preferred by the author (No. 1 for the first ligature on each broad ligament, No. 2 or No. 3 for the others), and they are to be passed by means of a long, curved needle fixed in a handle, and pierced near its point. The first ligature includes the upper third of the broad ligament, the round ligament, and the Fallopian tube. The latter is not to be penetrated by the needle. The second includes the middle third of the broad ligament, and the third its lower third; the latter also includes the trunk of the uterine artery. These ligatures must be passed

as far from the uterus as possible, in order to include healthy tissue, and must be tied firmly and with unusual care. The uterus should then be cut away from the broad ligament which has thus been secured, and the same procedure adopted with the remaining broad ligament. The ovaries are not to be removed. Hæmorrhage from small vessels is not usually abundant, but it is better to tie them whenever they are cut. Various modifications of this operation (which is attributed to Récamier) have been suggested by different surgeons for the purpose of facilitating the removal of the organ and giving greater security against hæmorrhage. The possible accidents of the operation are the wounding of the bladder or the ureters, in addition to the possibility of hæmorrhage, which is ever present. The shock experienced by the patient is usually not severe, and not to be compared with the shock which attends hysterectomy by abdominal section. After the removal of the organ the wound of the vagina may be left open (and the author thinks this a bad and a dangerous plan), or the edges of the wound may be brought together, a suitable opening being left for drainage. This means is all-important in this operation—far more so than in most cases of ovariotomy. The suturing of the peritonæum is neither recommended nor disapproved, the author frankly admitting his want of experience in this direction. The vagina is to be packed with iodoform gauze, or with salicylated cotton. This should be removed upon the second day, or sooner if the discharge is abundant, and should be renewed sufficiently often to insure healthy surroundings to the wound. The use of frequent vaginal injections is not approved. Sänger's statistics, published in 1883, show one hundred and forty-three operations, of which one hundred and thirty-three were for cancer, six for prolapsus uteri, and four for fibromata uteri. In one hundred and three cases the operation was successful, the patients recovering, at least for a time. The time varies from a few weeks to an indefinite period. In fact, reliable statistics can not as yet be made. Schröder, Martin, Lomer, and von Teuffel have had cases in which there was no recurrence after a year and a half or two years from the time of the operation. As a further element in favor of the operation, should reenrrence take place, the symptoms which accompany it are not likely to be so severe as those which accompany the primary disease. As to the mutilation which is caused by the operation, the author asks if it can be considered greater than that which follows operation for cancer of the tongue, œsophagus, or rectum.

Miscellany.

The Present Status of the Affairs of the Congress.—The "Maryland Medical Journal" says: "The new committee on the reorganization of the Congress, which held its meeting in New York on September 3d to 'repair the damages' occasioned by the resignations of the gentlemen appointed by the first committee, does not seem to have met with such marked success as its official organ, the 'Journal of the American Medical Association,' predicted for it. Indeed, so far from having repaired the damages previously inflicted upon the Congress by its Chicago work, this committee has made blunder after blunder until its action has become ridiculous in the eyes of the entire profession throughout this country and Europe. Its mistakes have been so glaring and faulty that one of its own number has been forced to show that its affairs have been conducted in the interest of its own officers, and that its deliberations have been so suppressed and manipulated that the reports of its meeting in New York were not in keeping with the facts.

"The committee has added another insult to the list of injuries previously perpetrated by its arbitrary assumption of authority. Through its Executive Committee it has formally declared that its acts are 'not subject to revision, amendment, or alteration by either the Committee of Arrangement or the American Medical Association.' In fact, it usurps all power and resolves to run the Congress according to its own methods. The result of this singular and unjustifiable procedure begins to be apparent. Within the last ten days a number of the appointees of the New York meeting have declined to accept the positions to which they were assigned. Such gentlemen as John C. Dalton, Henry I. Bowditch, Henry F. Campbell, Robert Battey, E. O. Shakespeare, and others have been forced to desert the sinking fortunes of an organization which has done nothing but trifle with the best interests of American medicine since it came into existence.

"Some weeks ago, in discussing the outlook for the Congress, we urged the present committee to resign, and gave, as we believed, satisfactory reasons for this advice. The resignation of this committee would have been a graceful act and would have saved the profession in this country from the mire of contention into which it has been cast by the unwarranted action of the association at New Orleans. The committee, however, saw proper to lay aside all considerations for the interests of the profession and entered upon the work of reorganization of the Congress in a manner agreeable to its membership. This committee has no one to censure but its own membership, if its action has failed to give entire satisfaction to the profession. It has proceeded with its work in the face of active and outspoken criticism, and it must stand or fall accordingly. We have believed that the work it was attempting to do was wholly unnecessary, and we have advocated its abandonment of this work on the ground that its continuation would promote nothing but strife and dissensions. We have never believed that the success of the Congress could be promoted by its interference. On the contrary, we have predicted that the Congress would fail if intrusted to its efforts. This prediction we believe will be shortly verified. The work of disorganization has continued, the breach has been made wider, and the affairs of the Congress are in a more pitiable plight now than at any previous time. If this committee now fails to see the handwriting on the wall which significantly tells of its downfall, we are at a loss to account for its stupidity and want of comprehension. Its continued effort to carry out this work of reorganization only increases the depth of its mortification and chagrin at its final overthrow. We would again suggest to this committee the advisability of gracefully stepping down from its present lofty but absurd and arrogant position."

In another article, the same journal says: "The present Secretary-General of the Congress has had nothing good to say of those gentlemen constituting the original Committee of Eight on the Organization of the Congress for having accepted positions in the various offices of their own appointment. How can the Secretary-General reconcile his own position in this respect? Virtually the American Medical Association and the International Congress are combined in his august person. He is more autocratic than the Czar of Russia."

A Philadelphia View of the Congress Organization.—The "Journal of the American Medical Association" publishes the following, in a letter from its Philadelphia correspondent, "C. W. D.":

"The questions in regard to the proposed meeting of the International Medical Congress, which were the subject of so much discussion when I last wrote, have ceased to be a live issue in this city. The action of the new committee in New York seems to leave nothing to be done but to wait and see whether the European men will come to America under the circumstances or not. It is believed here that they will not, at least not in sufficient numbers to give the meeting an international character. It is also thought by some, and hoped by others, who did not approve of all the acts of the original committee, that those who have charge of the interests of the Congress in Europe will decide to hold the next meeting in some city there—Berlin is spoken of as most likely. This, as one of the most conservative men in this city said to me a few days ago, would be the simplest way out of an awkward dilemma, and would furnish an opportunity for the present excitement of feeling to subside to the advantage of all concerned.

"I have heard some comment upon the action of the new Executive Committee in New York on September 24th, whereby they unanimously resolved that what they were to do was not subject to 'revision, amendment, or alteration' by the General Committee, which appointed them, or even by the American Medical Association itself. It is wondered here whether such a declaration of independence will be tolerated by the association when it meets in St. Louis, or whether it will send the committee out to read and reflect upon the opinion of Mr. Randall with which their predecessors were put to naught. Time alone can

show; but the members of the original committee are said to feel a keen regret that they did not at the start adopt this easy method 'to prevent all further misunderstanding, both at home and abroad.'"

The False Position of the Committee of the American Medical Association resolutely adhered to.—Under this heading the "North Carolina Medical Journal" says:

"Discussion, so far, has done little to stay the ruinous course pursued by the malcontents of the New Orleans meeting in regard to the International Congress. The new combinations of the Chicago and New York committee meetings have only made a bad matter worse. When we look back upon the whole affair from this standpoint, we can not help feeling that those gentlemen who represented the International Medical Congress made a very unwise move in asking the American Medical Association to take any part in the construction of the forthcoming meeting. These gentlemen would have done far better by taking the whole responsibility upon themselves, and this course would have been satisfactory to the members of the last Congress, the evidence of which we have in Sir James Paget's letter to Dr. Hays. The discourtesy of the American Medical Association toward the original committee seems not to occur to the reconstruction committee, and there can be but one interpretation of the whole matter—the new committee intends to organize a Congress upon a basis so objectionable that it has already divided the profession into two parties. If the gentlemen composing this new organization are willing to undertake it, they can not be prevented, but it would be well if they could be, both for the success of the Congress and the unity of the profession. We have written the above lest by silence it might be thought that this journal has altered its views upon the subject. The American Medical Association has made a false step, and it will be exceedingly fortunate if it recovers from it without estranging some of its most desirable members."

THERAPEUTICAL NOTES.

The Juice of the Fig-tree as a Digestive.—Signor Bianchi, of Florence ("Semaine méd."; "Lyon méd."), has ascertained that a drop or two of the juice of the leaves, or of the unripe fruit, will rapidly reduce a bit of fibrin to a *bouillie* soluble in water and giving the reaction of the peptones. This new agent is therefore likely to be of service in cases of dyspepsia due to defective secretion of the gastric juice. It should also be capable of taking the place of papain as an application to diphtheritic membranes and ulcers.

An Injection for Paralysis of the Bladder.—The "Union médicale" credits the following formula to Dumreicher:

Extract of nux vomica	3 to 6 grains;
Distilled water	6 ounces.

One sixth of the whole is to be injected into the bladder every day, and retained for an hour. At the same time, electricity may be used with advantage, and micturition is to be regulated as much as possible the urine being passed every four hours.

The Treatment of Inflammation of the Vagina.—According to the same journal, M. de Sinéty recommends the following liniment:

Subnitrate of bismuth	90 grains;
Crystallized carbolic acid	15 "
Glycerin	6 drachms;
Distilled water	3 ounces.

Cotton tampons soaked in the mixture are to be introduced into the vagina. They may likewise be moistened with coal-tar or covered with the following ointment:

Pyrogallic acid	150 grains;
Starch	225 "
Vaseline	1½ ounce.

At least two applications should be made daily, and care should be taken to carry the tampons to the very top of the vaginal *culs-de-sac*. They must be carefully freed from all excess of either liniment or ointment, as it would run out upon the vulva and create unnecessary pain.

Caustic Crayons.—Moser's formula (*Ibid.*) is given as follows:

Powdered charcoal	1 ounce;
Nitrate of potassium	1 drachm;
Porphyrized iron	75 grains;
Benzoin	15 "

Add enough adhesive powder to make forty crayons. These crayons are hard, light easily, and produce immediate cauterization, so that they are suitable for the treatment of poisoned wounds.

Direct Interstitial Medication by Dielectrolysis.—M. A. Brondel, of Algiers, brought forward a novel plan of medication at a recent meeting of the Paris *Académie de médecine* ("Rev. méd."). By the term dielectrolysis (*diélectrolyse*) he refers to a process for making a nascent chemical substance pass through the tissues. For example, taking iodine, a body which is readily "dielectrolyzable," he applies to any desired part of the person a compress wet with a solution of iodide of potassium, and over it he places the negative electrode of a galvanic battery, the positive electrode being held against any indifferent part of the body. The iodine leaves the potassium, and, actually traversing the intervening tissues, rapidly arrives at the positive electrode, as may be ascertained by testing with starch-paper. In effect, therefore, this is a hypodermic, or rather interstitial (*intra-organique*), method without wounding the skin or producing pain. As a great number of simple bodies may thus be made to penetrate from one point to another, the practical applications of the new method may be very numerous and very important. By it the author has cured fibrous tumors of the uterus, a case of perimetritis, a rheumatic ovarian neuralgia, and several cases of chronic rheumatism. He has in view further trials upon parasitic and malignant tumors, diseases of the skin, syphilis, neuralgias, etc., and especially pulmonary consumption, on which latter he proposes to try the action of various mineral antiseptics, such as arsenic, mercury, fluorine, etc.

Cocaine in the Treatment of Hay Fever.—In a paper lately read before the College of Physicians, of Philadelphia, Professor J. M. Da Costa said:

"The manner of employing the cocaine is not without importance. It may be used with a small atomizer as a spray. But the readiest means is to inject from five to eight drops up each nostril, the head being thrown backward; in some persons once, in most twice, daily will be found sufficient. It will be necessary to instruct patients not to irritate the membrane by rubbing it needlessly with the glass tube, or pushing this up too far. Thus, a patient who had had hay fever for thirteen years, and who was at the sea-shore on the 17th of August when the hay fever came on, and in whom tincture of *Ignatia amara* seemed favorably to influence its course, tried cocaine in one nostril only. He inserted the tube far up, irritated the membrane, and water ran from that nostril, which became sorer and more inflamed than the other. More judicious attempts produced better results, but he could not be persuaded to give the remedy a fair trial, owing to his first experience with it. Its mode of action in hay fever is partly by the local insensibility it produces, partly by the contractions of the capillaries it induces. The effects are thus chiefly local. It will not arrest the bronchial catarrh or the asthma which attend some cases; yet it is astonishing how it seems to lessen the tendency to these complications when early applied, and before they have got much headway. Is its action, then, not partly a reflex action? That the remedy is radical, and, strictly speaking, curative, I have not found; but that it gives great comfort, converts bad into light cases, enables those to stay at their homes who otherwise are obliged to flee to hay-fever resorts, relieves much suffering and distress, I know and have fairly tested. In no case of rose-cold or hay fever ought cocaine to be left untried."

Ethyl Compounds of Mercury.—In view of the present rage for testing all possible compounds of mercury in regard to their fitness for hypodermic use, Dr. P. Hepp, of Strassburg, has thought it wise to publish a sort of warning concerning some of the ethyl derivatives, in the form of a preliminary note ("Ctrlbl. f. klin. Med."). He has been engaged in studying the properties of ethylmercury and ethylsulphate of mercury, but he has not yet been able to look upon it as warrantable to use these dangerous poisons on the human subject, although the temptation to use them is heightened by the fact that neither an oily solution of the former nor an aqueous solution of the latter causes the slightest pain when injected under the skin. He refers to the sad results to two English chemists from inhaling the fumes of methylmercury.

Lectures and Addresses.

A SKETCH OF THE LIFE OF JAMES LAWRENCE LITTLE, M. D., AND OF THE TWENTY-FIVE YEARS IN WHICH HE PRACTICED SURGERY IN NEW YORK.*

By D. B. ST. JOHN ROOSA, M. D., LL. D.

James Lawrence Little was born, of Scotch-Irish and English ancestry, in the city of Brooklyn, February 19, 1836. He attended private schools in his native city until he was about twenty years of age, when he attempted to become a bookseller, and for this purpose became a clerk in a Fulton Street establishment kept by Mr. Riker. The firm that engaged him had a stock of medical books as well as of general literature. The young clerk was soon so deeply engaged in the study of these books that he proved a very inefficient salesman, and he soon gave up his attempt in business. This inclination to the study of medicine had already been seen in young Little when he was a mere boy. After much cogitation as to the ways and means of getting a skull for the purpose of study, he finally approached a venerable African grave-digger, who consented to furnish him with the desired relic if he would bring twenty-five cents and a paper to wrap it in. Young Little secured the treasure on these terms, and, returning home, took a peep at it, and, to his youthful horror, found that it was an unprepared skull looking upon him in the ghastly covering of facial integument and scalp. Fear got the better of his anatomical enthusiasm, and seeking a plan to get rid of what was now a source of dread at its horrible aspect, as well as fear lest he might be found with such an unexplainable object upon him, he threw it into the waters of Wallabout Bay, and postponed his medical studies for a season.

After leaving the bookstore, Little entered the office of Dr. Willard Parker as a private student, and at the same time he matriculated in the College of Physicians and Surgeons. After Dr. Little had become a distinguished surgeon, Dr. Parker gave the writer an account of how he nearly rejected him when he applied for entrance to his already crowded rooms. He was at first disposed to decline to receive another student, but he was impressed by the great earnestness of the tall and handsome young man, and he consented to take another student. "But," continued Dr. Parker, "I never had occasion to regret my decision. Punctually as the clock struck nine the click of the young man's step was heard upon the doorstep, and I got to recognize his step and to count upon him, whoever failed." The word *click* aptly describes the short and quick step that many of Dr. Little's contemporaries will recall as one of his personal characteristics.

After being in Dr. Parker's office more than two years he successfully passed a competitive examination, and was appointed a junior assistant in Bellevue Hospital. This appointment did not take effect until the following spring. Meanwhile, in March, 1860, he was graduated at the College of Physicians and Surgeons. He then resigned his position at Bellevue, and after examination he was appointed junior assistant on one of the surgical divisions of the New York Hospital. A resignation of a place in one hospital to take a similar one in another was something unusual, and it was said at the time that it caused a little unpleasant feeling among the staff at Bellevue, for Dr. Little was well known to some of them, and to James R. Wood in particular, as a promising man whom it was not well to lose.

Bellevue Hospital was just coming into some importance as a school of surgery, and chiefly through Dr. Wood's clinics and his prizes for anatomical preparations offered for competition among the medical schools. Yet at that time it could in no manner compare with the New York Hospital in furnishing opportunities to a surgical student. It was an institution belonging to the city, receiving only paupers to its wards, and it was governed by politicians. It had much more importance as a school of medicine than as one of surgery. Dr. John W. Francis was one of its consulting physicians, and occasionally gave a mellifluous and learned address in its amphitheatre, and Alonzo Clark, John T. Metcalfe, and Benjamin W. McCready held clinics in the wards, while on Saturdays there was a great crowd of students to witness the rapid and skillful surgical operations of the renowned pupil of Valentine Mott, James R. Wood. Certainly any young doctor in medicine might have been honored by entrance into such a hospital. But the New York Hospital was a wealthy and private corporation, governed by some of the best laymen in the city, and, more than all, it was one of the most renowned schools of surgery in the world. In its amphitheatre Wright Post and Kearney Rodgers had won their fame, and here Valentine Mott, who was still living and lecturing upon surgery, had tied the arteria innominata. He was consulting surgeon with Alexander H. Stevens, John C. Cheesman, and Alfred C. Post. Of these, but one now remains, an honored link to connect us to the medical New York of fifty years ago. The active members of the surgical staff were Gurdon Buck, John Watson, Thaddeus M. Halsted, Willard Parker, William H. Van Buren, and Thomas M. Markoe. Of this number but one now survives, and he happily in full vigor of mind and body.

The old hospital was beautifully situated on Broadway, facing Pearl Street, on ample grounds, with grand old elms. Its beautiful lawn, upon which tame deer might often be seen, was a surprise and delight to the strangers in New York, who came suddenly upon this break in the whirl of a great city. The house staff was in a traditional state of excellent discipline. Its members vied with one another in their care of their cases, and their dressings of fractures and ulcers were at once the delight and dismay of medical students, who followed the attending surgeons about the wards. It was not strange, then, that young Little, especially when urged by his preceptor, resigned his place in a hospital which had no past for one whose annals, twenty-five years ago, were more full than perhaps any surgical hospital in the land.

* Read before the New York Academy of Medicine, November 5, 1885.

In April, 1860, Dr. Little began his duties at the New York Hospital as a junior walker. In April, 1885, he died. Hence, it may be truly said that a quarter of a century bounded his professional career. What a twenty-five years it has been for medical and surgical science in New York and in the world! There were then three colleges and perhaps eight hundred students and practitioners attending lectures in the College of Physicians and Surgeons in Twenty-third Street, the University in Fourteenth Street, and the New York Medical College in Thirteenth Street. Bellevue Hospital Medical College existed only in the embryo of its medical clinics and James R. Wood's exploits on Saturday afternoons. Clinical instruction was in its infancy, and there were but two hospitals, at long distances from the colleges, where it may be said to have existed in a meager way, and then to be attended by not more than a score or so of the students, except when a great operation was to be performed. Now there are added to the New York and Bellevue, the great Charity Hospital on the Island, St. Luke's, the Roosevelt, the Presbyterian, Mount Sinai, and St. Vincent's; these are all more or less used for clinical teaching, and eighteen hundred or more students and physicians attend the lectures of the three colleges of our faith, the College for Women, the Post-Graduate School, and the Polyclinic. Among the most widely known of the teachers at the colleges were Parker, Gilman, Watts, St. John, and Joseph M. Smith, in Twenty-third Street; John William Draper, Bedford, Paine, Van Buren, Post, and Metcalfe, at the University; Horace Green, Fordyce Barker, Ogden Doremus, and Carnochan, in the New York College; while George T. Elliot, Charles A. Budd, Loomis, Jacobi, Thomas, and Sands were, as would be said in Edinburgh, *extra-mural* teachers, who were nearly within the walls. As we recall many of these names, the words of the Latin poet come at once to our memory:

> "Eheu fugaces posteum posterum,
> Labuntur anni."

When Dr. Little entered the New York Hospital the civil war had not broken out, although exciting meetings of students had been held on account of the John Brown raid, and Southern students were being pledged not to return to Northern cities for instruction. Terrible strife was soon to cause the erection of immense hospitals by the medical staff of the United States army, from whose records surgical literature was to be enriched to an extent not dreamed of by the surgeons of this country. The battle-fields of Manassas, Shiloh, Gettysburg, and around Richmond were, from their awful experiences, to train a race of men which has caused American surgery and medicine to take a higher place in the world than would have been attained by half a century of work in small civil hospitals, while the Sanitary Commission was to open up a field for the cultivation of sanitary science and of active benevolence hitherto unknown.

When Dr. Little entered the wards of the New York Hospital the thermometer was not used to show the temperature of the body. The laryngoscope and ophthalmoscope had just been placed in the hands of a very few specialists, but they were not at all employed in the New York general hospitals. There was but one hospital of any considerable importance for diseases of the eye and ear, and that had not one half the number of patients it now has, although three similar institutions have been added to the charitable and educational resources of the city. There were no training-schools for nurses, and scarcely any trained nurses worthy the name. Those whom we had were chiefly males, who had been promoted from being patients to be nurses, with a strong preference for alcohol as a stimulant, while the women, in many instances, had been scrubbers in the wards over which they now presided. Not but that there were some excellent nurses in those days, however. Pyæmia, erysipelas, and hospital gangrene were then dreaded foes, and antiseptic surgery, if practiced in attempts at absolute cleanliness, was not understood as now, when patients, after operations, are saved, not as by fire, but as a matter of course. Marion Sims was just about to found the Woman's Hospital and become the intellectual progenitor of men who with him created modern gynæcology. All this Dr. Little saw, and in much of it he was an active participant.

New York, in 1860, had two or three medical journals, not of extended circulation, while an Ishmaelitish scribbler or two issued monthly bulletins in a style of medical journalism now happily extinct. There were two medical bookstores, called publishing-houses rather by courtesy than as a matter of fact, for no New Yorker wrote a medical book, and very few even edited or translated one. New York scarcely claimed equal rank with Philadelphia as a medical center. Now New York boasts three publishing-houses where American medical books are issued, and that in considerable number. Her medical journals are more widely circulated than those of any other city in this country, and they are to be found by the side of the works of American medical men upon the library-tables of the physicians of every nation.

In the hospital, Little gave promise of his future career. He was assiduous and faithful as an assistant, and suggestive and enthusiastic as a house surgeon. His humorous contemporary, Dr. Samuel W. Francis, remarked of him, that even then there was *multum in parvo*. He reported many of the cases occurring in the wards in the "American Medical Times." It was while in the hospital that he devised his method of making and applying plaster-of-Paris splints. It is not too much to say that chiefly, if not entirely, through Little's efforts plaster-of-Paris splints became a practical application. Until then, although much recommended, experience had shown that it was not well adapted for a surgical dressing. Little saw in plaster of Paris a material which, if properly used, would form that so much to be desired, an immovable and yet porous splint. Those of us who were associated with him remember his painstaking trials in preparing the plaster, in securing the proper consistency, and the material best adapted to take up the solution; the disappointments and failures until a splint was produced which convinced his colleague, the house surgeon of the other division, and the attending surgeons, that the days of the starch apparatus, a favorite bandage of the hos-

pital, were past. In using plaster of Paris as a splint instead of a bandage, he utilized the material as never was before done, and although it is possible that it will never have a widespread use, just as Dr. Little employed it, he gave an impetus to the subject which was perhaps the origin of the famous plaster-of-Paris jacket. His paper upon the subject may be said to be classical.*

During the civil war, on several occasions, Little's services were furnished to the Government. He was for a time surgeon-in-chief to the hospital erected on the edge of the City Hall Park, and twice, at least, after great battles, he volunteered with those other New York surgeons who went to the front at the call of the Surgeon-General. Now, as then, the avenues to professional success as a teacher and consultant began at service in dispensaries and clinics. Dr. Little was engaged in such work from the days when he was a medical student and a *substitute* for the junior walker in the hospital until his death. One year after leaving the hospital he was appointed clinical assistant to Dr. Parker, who was then professor of surgery in the College of Physicians and Surgeons. In 1863 he was appointed a lecturer in the college. His first course of lectures was upon "Fractures and their Treatment." These lectures were continued until 1868, when his chair was enlarged to that of "Operative Surgery and Surgical Dressings."

Dr. Little was very popular as a lecturer. His manner was exceedingly simple—in fact, at first distressingly so; but it was earnest and devoid of mannerisms and self-consciousness. One of our most successful teachers lately said to me: "Little did not merely tell the men to apply a flax-seed poultice, but he brought the flax-seed and the cloth to the lecture-room and made the poultice before the class. Then they knew how it was done, for they had seen it." Indeed, his teaching was realistic to a degree. The man was thoroughly in love with his work. He was alive to every progressive tendency; he traveled in no rut, but was always on the alert to assist in making surgery the exact science it is so fast becoming. He took great pains with the illustration of his subject by diagrams and drawings, which were prepared by competent men under his directions with great care. An examination of his library after his death showed that he had ransacked the surgical pictures of Great Britain and the Continent to secure the best illustrations for his lectures. Certain it is that not a little of the fame of his alma mater for thorough teaching was due to Dr. Little's lectures, although they were given in the summer term, and attendance upon them was not obligatory. They were continued for sixteen years, when he resigned from the position he held in the college as a lecturer on surgery, and one of the staff of Professor Markoe, who has succeeded Parker, to accept the appointment of professor of clinical surgery in the University of New York.

But Little's best qualities as a surgeon, a teacher, and an executive officer were seen after his acceptance of the chair of surgery in the University of Vermont. This was in 1875. He had previously declined an offer of a similar chair in the Long Island College Hospital. He entered upon the work in Burlington with great zeal. There he found a medical college that still survived the vicissitudes of forty years, although those at Woodstock and Castleton, in the same State, had been abandoned. It had about sixty students. Little's keen perception of the possibilities of this field showed him that they were great. The lately elected president of the University, Dr. Buckham; the venerable Carpenter, professor of practice; with Thayer of anatomy, King of obstetries, and Darling of anatomy, were fully alive to what lay in store for the Burlington Medical College. There was a reason for the existence of a medical college there. It was needed to supply the demand for medical education for a large number of young men from Vermont and northern New York, who could not conveniently go to Boston, Philadelphia, or New York.

The academical department, at the laying of whose corner-stone Lafayette had assisted, embraced in its faculty many soundly educated and cultured men, whose sympathies were readily enlisted for any good scheme for the cultivation and dissemination of human knowledge. They seconded the efforts of the president to give character to the various departments. The medical school acquired a certain dignity by its name, and it had that not unimportant advantage over the schools that formerly existed in the same State. Many young men, exceptionally well prepared by previous training, found it more convenient to study in Burlington, on account of the greater expense attending a long stay in a large city; and many practitioners of Vermont and northern New York found the clinics and lectures of the medical department of the University an accessible post-graduate school, which lighted up many a dark subject, and gave them a little recreation from their lonely and responsible duties as country physicians. The professor who went to Burlington from a metropolitan medical college soon saw that he had as intelligent and as earnest listeners as at home, and that he must relax nothing in his efforts to teach his science and art. With the hearty co-operation of the president of the University, who presided at all the faculty meetings, and his own colleagues, Professor Little immediately began to devise plans for increasing the fame and usefulness of the school. By personal solicitations in many instances he was largely instrumental in securing courses of lectures and clinics upon subjects not fully, if at all, embraced in the general curriculum, by specialists from colleges in our city. Then Miss Mary Fletcher, acting largely upon the advice of President Buckham and Professor Carpenter, founded a hospital, and, with a broad-mindedness not always seen in those who found hospitals, gave up its wards unreservedly to the teachers of the college. This was naturally of the greatest importance to the success of the school, for the day had passed when didactic lectures unillustrated by subjects were considered fit means of teaching medicine and surgery. Little's facilities for the performance of great operations were largely increased by the foundation of the hospital. His clinics were sought by crowds of patients from far and near. During the weeks that he lectured in Burlington the streets of the town gave evidence, by the passing through them of numerous people with surgical dressings on some part of the body, and by the great accumula

* "Trans. of the Am. Med. Assoc.," 1867; "Med. Record," 1874.

tion of the mud-stained buggies of the practitioners of the adjacent towns, as well as by the over-filled wards of the hospital, that a great deal of surgical work was going on. Stimulated largely by Little's surgical feats, and by an executive capacity heretofore, from the want of an arena, not known to belong to him, the college grew apace in character, in importance, and in the number of students. A new building was given to the faculty in 1884, by the late Mr. Howard, and, when Dr. Little died, more than two hundred and twenty students in the class-rooms of the college mourned the loss of their professor of surgery.

In an address commemorative of Darling and Little, Professor A. F. A. King sketches the introduction of the latter to the class in a manner so graphic and descriptive of the man that it is here reproduced. Dr. King says: "I introduced him to the class, and I well remember his modest embarrassment, which would, however, have passed unnoticed by the students had he not said, in the course of his first disjointed remarks, 'I'm a little nervous, as you see.' But a patient was introduced, a diagnosis made, an operation decided upon, and a knife handed to Professor Little, and I can tell you (as you know) he was not nervous *then*."

To those of us who knew Little well it was interesting to see this preliminary nervousness when a great operation was imminent. The quick, short steps, the restless tapping of the foot when he was preparing for his work, gave little promise of the bold, self-reliant man as he stood over the patient, perhaps reeking with the perspiration of surgical ardor, but yet with steady, skillful hand working in a manner that convinced any one, competent to judge, that a life given into his hands would be preserved and returned, were it among human possibilities.

In Burlington, as in New York, "Little's luck" became proverbial, for his operations, from causes that I am not able to analyze or define, were pre-eminently successful. A well-known surgeon in New York told me, in substance, that it was a prevalent opinion in St. Luke's Hospital that it would be safe for Little to cut off a foot of an intestine, when another man could hardly touch it with a knife; and yet he was deferential to a fault to the surgical opinions of his peers, ready to adopt their suggestions, and to give proper credit for them. He was a man who exhibited great common sense as a surgeon. He was not overtrained, but he knew how to get at the upshot of a case without being unduly anxious as to how Esmarch or Lister was doing that thing now.

Dr. Little's chair in the University of New York was never a satisfactory one to him. His clinics there were held but for a part of the session, and he taught but once a week, although his classes were large, and the students, at least on one occasion, petitioned the faculty that his instructions might be continued throughout the session. The request could not be granted, on account of the pressure for time in which to give the whole curriculum. Three years after his acceptance of the position, together with six members of the former post-graduate faculty of the University, he resigned, in order, in conjunction with them, to establish the New York Post-Graduate Medical School. To this institution he gave the same hearty effort that he displayed in Burlington. His lectures to graduates were, if possible, better appreciated than by the under-graduates whom he had instructed since his early manhood. A doctor was to him a brother. Without quite knowing it himself, he acted as if he supposed that every man who sought or had acquired the degree of M. D. was as eager and honest in the pursuit of knowledge with which to save life and mitigate disease as he was himself.

It is said that he always leaned toward the student, and possibly too much, when required to vote upon his examination in the faculty at Burlington. This was not from any idea of lowering the standard of proficiency, but because he could not be made to understand that there were men who, unlike himself, regarded medicine as a business, in which they were willing to embark with as little capital as could make a fair show. During these last three years he exhibited his best qualities of faithful work, and if, as Dr. Lloyd, one of his former office students and valued assistants, says, "he was inclined to throw off his work on other shoulders, and less inclined to undertake long and serious operations," on account of some grave symptoms in his general health, it was not apparent to those of his friends who saw him only at intervals. The last public work he was engaged in was a meeting of the Post-Graduate Faculty, on the evening of March 31st, when he appeared in his usual health and spirits. At that meeting an incident occurred which was characteristic of the man. He felt impelled by his judgment to vote, on a question which then came up, contrary to his feelings. It was a question that might affect the interests of some to whom he was attached, and, after he had voted and he was found to be in the majority, he expressed his regrets that he should be obliged to vote for a policy which might prove detrimental to the interests of a friend, and he vainly sought for a compromise upon the subject.

Dr. Little's services to St. Luke's Hospital were very great, and they were warmly appreciated by his patients, his colleagues, and the management. He served one term of ten years, from 1868 to 1878, when he was retired under the rules to be made a consulting surgeon. In 1882 he was reappointed an attending surgeon, and held the position until his death. Little used to tell a story of an experience of his at St. Luke's which well illustrates the maxim that "all men think all men mortal but themselves." He was to operate, on one afternoon, upon two cases for resection of the upper jaw. The first patient died upon the table from getting blood in the trachea, and Little sent word to the survivor that he wished to postpone the operation for him. He was very much disappointed at the delay, and urgently insisted that Dr. Little should personally visit him in the ward and tell him why he did not wish to operate upon him as appointed. The surgeon accordingly went up, and with some hesitation, on account of the probable effect upon the hopes of the candidate for an exsection, frankly told him that the first man was dead, and he did not feel like going on with a case of the same kind just at the moment. But instead of being daunted the patient exclaimed, "Oh, that's nothing! I'm not afraid. The other man was a sickly

fellow. I never thought he would get through. You operate on me. I won't die." As a matter of fact, Little did soon operate upon him, he got no blood in his trachea, and he did not die.

In 1876 Dr. Little was appointed an attending surgeon to St. Vincent's Hospital, a position which he held when he died. Little always believed that the kind offices of the Rev. Vicar-General Quinn, one of the managers of that hospital, were largely instrumental in securing him this position. The Vicar-General was a priest in the wards when Dr. Little was house surgeon in the New York Hospital, and in his visitations to the sick and dying in the wards had been struck by the commanding presence, the assiduous and faithful labors of the young surgeon.

Of Dr. Little's surgical achievements in detail I am not competent to speak, nor is it necessary that I should do so. They are indelibly recorded in surgical literature—at least in part, for of late years Dr. Little was somewhat regardless, from lack of time, perhaps, from his large and exacting public and private practice, to write as much as his friends might have wished. But I may say that he was the first American surgeon to puncture the bladder with the aspirator for the relief of retention of urine. He simultaneously ligated the subclavian and carotid arteries of the right side for aneurysm of the fine part of the subclavian. The operation for stone by various methods he had performed seventy-seven times, with a fatal result in but two cases. In hare-lip and strangulated hernia he also had a large and successful experience. He entered into the advances claimed to be made by antiseptic surgery with great enthusiasm, and on his last visit to Europe, at the meeting of the International Congress in London, he investigated Lister's methods very carefully, and came back to carry out all the details of Listerism in capital operations. He was a surgeon who looked round upon a far horizon. Very few operations were foreign to his knife. Yet he was extremely appreciative of specialists, and, while not heeding their advice so much as some of those who have looked askance at them, he frequently sought their aid, and often publicly recognized their value in enlarging the field of exact knowledge. He himself used the ophthalmoscope, the laryngoscope, and other means of examination not always used by general surgeons, so that he was singularly competent to make an examination in any surgical case. In the practice of medicine also—for he by no means confined his work to surgery—he was suggestive in the matter of treatment, and had many celebrated prescriptions upon which he drew with great readiness and accuracy.

Little was a great admirer of his instructor, Willard Parker. He gave his first-born the name of his preceptor. Dr. George Shrady styles him one of his worshipers. So great was this admiration when he left the hospital that some of his friends feared he would be content to be an imitator and never strike out for himself. He seemed to have acquired Dr. Parker's art of making surgery fascinating to students; he drew them about him in great numbers. Even if the clinical material for his hour, on any particular day, was scanty, the lecture would not betray the want, for what was there was made the subject of homely but important lessons. The capacity for dignifying the every-day work of surgical practice, for making apparently minor things and details assume their true importance, belonged to him in a great degree. He could make a good clinic from material which some surgeons would not deign to spend a moment upon. Like Willard Parker, also, he attracted to himself numerous office students, who almost invariably became much attached to him.

Dr. Little was, in the good sense, a simple-minded man. He loved to sit down in such places as the office at the hotel in Burlington, and, as he became warmed in his discourse, talk to plain laymen, who understood but half of what he said, of tumors and ligations, of resections and ovariotomies, and all without any idea of boasting of his own deeds, for he had not the faintest resemblance to a braggart, but he was so interested in surgery that, like Agassiz, who talked about his study of the skeletons of fishes to stage-drivers, he fairly bubbled over upon the subject. He was fond of the meetings of the profession. After its foundation, the New York Surgical Society was his favorite place for recounting his experience and listening to the discourse of the distinguished men who organized and maintained this body. He was one of the signers of the address to the profession of the State against the re-enactment of the Old Code, and the movement to liberalize the profession had his full sympathy and co-operation. Social to a degree, he could be found late in the afternoon in the conversation-room or at the monthly meetings of his club, with a cigar for himself and for his neighbor, ready to discourse upon any subject that was uppermost in men's minds. He gave great thought and spared nothing in the education of his two sons and a nephew. He had almost exaggerated ideas of the importance to a young man of an exact and thorough course of study in a college. He did not practice his profession with an idea of amassing a fortune, but he conceived that it was better to thoroughly educate his sons than to leave them the few dollars which a niggardly economy might have allowed a physician dying in middle life to put aside from his professional income. Before his death he had the great satisfaction of seeing his eldest son fully equipped and prosperously entered upon the practice of a lucrative profession. In his latter years he interested himself very much in the study of china and bric-a-brac. It became a recreation to him to visit auction-rooms, and often he came away with a rare bit of some kind.

Galton describes a certain class of men as being incapable of advancing beyond a certain point in mental attainment, just as another class can only be developed physically to a certain inferior standard. Little was not one of these. As long as he lived he grew in mental capacity. He was never satisfied with his own preparation for the study of medicine, but, while he did not enjoy the advantages of a college training that he appreciated so highly in others, he had that which no conventional curriculum can of itself furnish—a receptive, inquiring, and unbiased mind in science; and as to merely scholastic attainments he might have well said as did John Hunter when he heard that he was reproached by a rival with being ignorant of the dead languages, "I would endeavor to teach him on the dead body that which he

never knew in any language living or dead." It has been said by one biographer of Dr. Little that he was a typical American. It is certainly true that his career is a striking example of how eminence in our profession is to be attained by the resources of our own country. His education was wholly obtained within his own city. He had none of the advantages so useful to the best of men, so without use to many, which are to be obtained in British or Continental schools. But no man more than he appreciated the labors of foreign surgeons and pathologists, no one followed more eagerly the medical literature of his time; but he was fortunate enough never to acquire that slavish esteem for books which would have led him to read so many as to cease to think for himself.

The sense of humor was fully developed in Dr. Little. From the busy and sometimes weary life of a general practitioner, and from the society of his friends, he extracted much to give zest to his work. A joke at his own expense was almost as welcome as if for another. He used to tell with great glee, and awaking much laughter as he did so, how a little trick of his to stop too prolix patients once got him into great trouble. He said that he had found a good device for interrupting a needlessly long story on the part of a patient was to ask, in the midst of the long narrative, "Please let me see your tongue." He found that patients bore this interruption very well, and that, in their eagerness to get the doctor's opinion of this index of the digestion, its wagging ceased. But on one evening a friend, who was in no sense a patient, was making a call upon him, and talked long, when Little was very tired. After a time the doctor's mind wandered afar off from the discourse to the discussion of medical cases and questions, and, turning to his friend, who was in the full tide of talk, he asked with great gravity, "Please let me see your tongue." Little was never able to explain what happened when his friend had fairly taken in the meaning of this interruption.

But I must turn from the contemplation of the varied sides of our late associate's life and character. A quarter of a century was to be the limit of his professional life. In the apparent ripeness not of old age, but of middle life, it was ordered that his work should end. As has already been intimated, he was actively engaged at a professional meeting up to a late hour on Tuesday, March 31st, and on Saturday, April 4, 1885, he was in the life beyond. In August, 1884, it was discovered that he was suffering from diabetes. I believe it is thought, by some authorities at least, that the debility induced by this disease, the existence of which was shown by the examination after death, made him less able to resist the acute affection from which he died. At any rate, it had a sensible effect upon his apparent feelings and actions, as observed by his intimates. His thirst was marked, and he became much fatigued upon slight exertion. But he continued his daily work, without creating a suspicion of the existence of any serious disease, in those who saw him only at intervals, until Wednesday morning, April 1st, when he called his friend, Dr. Lloyd, to his office, at about ten o'clock, and he found him with his head resting upon his hand and complaining of a severe pain in the right iliac fossa.

He asked Dr. Lloyd to attend to his clinic for that day, while he proposed to make one or two calls in the afternoon. He then went up stairs and took a dose of cathartic medicine prescribed by himself. At noon he said he felt better, and he went out to try and finish some work, but he soon returned, complaining of severe pain. His family physician, Dr. John S. Campbell, was sent for in the evening; when Dr. Campbell arrived he ordered a dose of castor-oil, which he had seen relieve similar attacks in Dr. Little. The night passed without a movement of the bowels, and with a steady increase in the pain. Early in the morning he sent for Dr. Lloyd and gave him the necessary instructions in regard to his practice. When Dr. Campbell came for his morning visit he advised that Dr. Loomis be sent for in consultation, and when he came, although he thought there was beginning typhlitis, he advised a dose of calomel. He also had seen Dr. Little in similar attacks, which had been relieved by cathartics.

No alleviation of the pain was obtained, nor did the bowels respond to the frequent calls made upon them; and on Friday, owing to the increase of the pain, it was found necessary to resort to the hypodermic injection of morphine. It was also noticed that there was a localized peritonitis, and, when Dr. Campbell arrived, Dr. Sands was also called in consultation. By the time he arrived, in the afternoon, the inflammation of the peritonæum had become general, and it was a question whether it would be wise to operate. This was advised against, however, when the existence of the constitutional disease was fully considered. Although the hypodermic was used freely all Friday night, it was found on the morning of Saturday that the peritonitis was much aggravated. On this morning he sent for Dr. Lloyd, and when he got to the room he found him, in spite of the peritoneal inflammation, sitting in a chair by the side of the bed. As Dr. Lloyd entered the room he asked if he thought he looked much worse than the day before, and then immediately began to give instructions with regard to some business for the University of Vermont, which he thought ought to be attended to without delay. It was suggested to relieve the distension of the bowels by an aspiration, but he objected, and the matter was not urged. Dr. Lloyd, from whom I received these particulars, then continues: "After remaining with him for some time, I left to attend to the calls, and was probably absent about an hour. Upon my return I was met at the door by one of the servants, who asked me to hurry to the room, as the doctor was worse. Hurrying up stairs, I found Drs. Campbell and Powell already there, and that collapse had set in a few minutes before. Just before my arrival the doctor had asked Dr. Campbell, 'Doctor, don't you think a little digitalis would be good for this failing heart of mine?' Dr. Sands was also sent for and arrived in a very few minutes; but there was nothing to be done, and we now knew that the end was nearing fast. As I entered the room the doctor held out his hand with the expression, 'Lloyd, I am going now'; and then, a minute later, again calling me by name, he said, 'I now realize the truth of what poor Beard said.'* Dur-

* This refers to the dying words of the late George M. Beard, in which he expressed his regrets that he could not express the thoughts of a dying man.

ing all this time he was suffering intensely, but his mind was entirely clear, and his spirit undaunted by the fast approach of death. He summoned the household servants and family about his bedside, casting anxious glances at a clock that was in his chamber, plainly showing that he was counting the moments that he still had to live. Having bid farewell to each one by name, and with the words, 'I die in the Christian faith' upon his lips, there was a final instant of distress, when this brave man yielded up his spirit to the God who gave it."

CASES IN ORTHOPÆDIC SURGERY.*

By AP MORGAN VANCE, M. D.,
LOUISVILLE, KY.

Mr. President and Ladies and Gentlemen of the Kentucky State Medical Society: As your Committee on Orthopædic Surgery, I submit the following cases in operative orthopædy as my report, prefaced by a few remarks in justification of the procedures in three of the cases.

The ailment known as infantile paralysis is, and always has been, the dread of the orthopædist. It is productive of almost half the cripples we meet, and is dreadful because of the meager results attained by treatment, most of the authorities now holding that all relief derived comes spontaneously, and the effects of treatment other than that to prevent deformity and to promote locomotion are nil. This has certainly been my experience so far in the effort to revive the muscles which are lost.

The use of mechanical appliances for the purpose of gaining the above-mentioned results is very unsatisfactory for a number of reasons.

If we make apparatus strong enough to render constant breaking less liable, it will be too heavy for the weakened patient to manipulate at all, hence most patients soon discard braces, either because of this or from their inability to bear the expense of constant renewal. Deformity soon takes place, and, as the patient grows older and heavier, hopeless crippling is inevitable.

How many of these persons are daily seen on our streets! some unable to help themselves at all, others showing every degree of deformity with more or less disability. The mechanical surgeon, therefore, is constantly on the alert for new suggestions toward treatment.

It has been suggested, I believe, in England, and in some cases acted upon, though the results have not been reported, that the residue of the paralyzed muscles have a section removed, thus gaining by an inelastic band better control of the joint below. It has also been recommended, whether carried out yet or not I am unable to say, that in some forms of talipes calcaneus, for instance, the tendo Achillis be resected, thus gaining an inelastic band, as mentioned above.

* Read before the Kentucky State Medical Society, June 25, 1885.

The third suggestion, and the one I have taken advantage of, is to excise the useless joint and produce bony ankylosis, thus doing by bone what we attempt to do by apparatus.

This seems at first glance to be very bold surgery, but, when we look first at the utter hopelessness of these unfortunates, and at the fact that the joints are alive and the bone in young subjects healthy, we may hope for less risks than when we get our prognosis from statistics of excisions where bone disease exists. The greatest difficulty is the gaining of the patient's consent. No surgeon should ever perform any grave operation which is proposed for convenience without making the patient cognizant of the risks he is undergoing. First, because it is not right; secondly, because if it fails and the possibility of failure has not been explained, it renders surgery too unpopular in that neighborhood.

The authorities for this class of operations are very meager. In the latter part of 1881 I saw it mentioned in a journal that Volkmann had suggested this procedure for the knee and ankle where the muscles of the hip were left, and that four or five operations had been done, with what results I have not yet learned.

Not until May, 1882, did I succeed in getting a patient to consent to the operation.

Case I.—*Boy, aged Nine, Subject of Extreme Valgus from Infantile Paralysis; Unsatisfactory Use of Apparatus for Several Years; Artificial Ankylosis produced, with Good Locomo-*

Fig. 1 (Case I.—Before excision of the ankle joint.

tion resulting.—Ed. Lawrence, aged nine, of German parentage, came under my care as a dispensary patient in the early part of 1882, giving the usual history of infantile paralysis occurring at two years of age. Both limbs were at first affected spontaneously, recovery taking place to such an extent that only partial paralysis of the left lower extremity remained, producing, as the cut will show, a bad valgus.

He had been treated by various physicians, and had worn all forms of apparatus without material benefit either as to the cure of the paralyzed muscles or to locomotion.

At the first examination I proposed the operation of excision of the ankle joint for the purpose of causing stiffness in the best position for future usefulness, thus getting rid of all braces, which had been faithfully tried.

Not for several months did I gain the consent of the parents to the procedure, but finally, finding the foot fast assuming a worse position as the boy grew heavier, and the brace more often out of repair, consent was obtained.

Fig. 2 (Case I).—After excision of the ankle joint.

On May 13, 1882, the operation was done, Dr. J. W. Holland administering the chloroform, and several other professional friends being present. A well-fitting, adjustable splint, made of leather and hard rubber, had been prepared to receive the limb.

The first step, after applying Esmarch's bandage to the limb, was to make an incision, some three inches long, half way between the internal malleolus and the tendon of the tibialis-anticus muscle in the axis of the extended foot, the center of the incision being over the annular ligament.

When the joint was reached was it was opened and the foot broken off the tibia, the ends of this bone and the fibula being sufficiently exposed to allow of their being removed with the ordinary amputating saw; then the upper surface of the astragalus was shaved off with a stout bistoury through the cartilage and sufficiently into the bone to insure that enough surface would be freshened to produce bony union with the tibia and fibula. The wound was closed with stitches, a counter-opening being made for a rubber drainage-tube. No bleeding being present except from the shaved surface of the astragalus, this was stopped only after bruising the surface with the handle of the bistoury.

Surgical fever in this case ran as high as 102° F., but no very alarming symptoms occurred, and within three weeks the external wounds were closed. I think this would have occurred earlier had it not been for the great secretion of synovia, which caused the wound to open several times.

Three years have now elapsed, and this boy has been able to walk without apparatus and with no inconvenience. There is at this date three quarters of an inch shortening of that limb, with bony union of the astragalus to the tibia and fibula.

A mistake was made at the first dressing of the foot by placing it in slight extension, hoping thereby to more easily overcome the effects of shortening by simply extending the heel of this shoe. I believe this makes him step off this foot in valgus still, despite the fact that the foot was set in varus; and has produced, by the greater strain, weakening of the ligaments anterior to the astragalo-tibial junction. From this mistake, the result is not so good as it would have been if the foot had been placed at right angles, though the result obtained decidedly justifies the means.

Case II.—*Boy, aged Seven; Subject of Infantile Paralysis, of Six Years' standing; Partial Spontaneous Recovery of One Limb, the other almost completely Powerless and Greatly De-*

Fig. 3 (Case II).—Before excision of the knee joint.

formed; No Locomotion without Crutches; Excision of Right Knee followed by Bony Ankylosis, with Relief of Deformity and Great Improvement in Walking.—Charley Hadfield, aged seven; subject of infantile paralysis since ten months of age, both lower extremities being affected; the left had spontaneously improved to such an extent that, comparatively speaking, it had become quite useful.

Many forms of apparatus had been worn and every known treatment had been tried, and, from the history, I should judge very faithfully.

The photographs will better show this child's condition than I can by any written description. Suffice it to say, as the boy grew older he more fully realized his helpless condition, and kept complaining that his father would not have anything done for his relief.

The case came under my observation three years before its last appearance, and I had then advised the operation afterward done. The father, remembering this, came again and consented to it, after understanding its full gravity and assuming his share of the responsibility.

Fig. 4 (Case II).—After excision of the knee joint.

I went so far as to let him hear a discussion upon the propriety of this form of operation by the members of the Medico-Chirurgical Society of Louisville, which was not at all favorable to its performance.

On October 21, 1884, after an open splint, made of leather and hard rubber, had been prepared, the operation was done in the presence of a number of professional friends, Dr. J. M. Ray administering the ether.

As shown by the photograph, the limb was greatly deformed, the leg flexed, rotated, and partially luxated outward and backward. On account of this deformity, the first step in the operation consisted in making an incision longitudinally along the inner border of the patella, having for its center the joint. Before turning the bones out to be sawed off the patella was removed, then the ligaments were divided and the ends of the femur and tibia easily exposed and removed with an amputating saw. There was no hæmorrhage, as in Case I, as the sawing closed the cancelli. The external ham-string was left untouched, it being the only muscle of the thigh which had any vitality left, and by its contraction had produced luxation and rotation of the tibia. This muscle served as a perfect tension band to hold the bone in apposition.

There was little or no shock following the operation, and the limb was at once placed in the splint. Ten hours after the patient was placed in bed the temperature was found to be 105° F. Reasoning that nothing but malaria developed by surgical procedure could produce such a fever as this in so short a time, quinine was used liberally with the effect desired, and had to be kept up for a considerable time.

The boy suffered little during his convalescence, and was confined in bed for eight weeks before the wound closed; during this whole time there was an excessive discharge of synovial fluid, as in Case I. His general health was much improved, as will be noticed by the difference in his appearance as shown by the photographs.

The only accident occurring during his convalescence was at about the end of the third month, when the wound and counter-opening reopened completely, following the formation of pus.

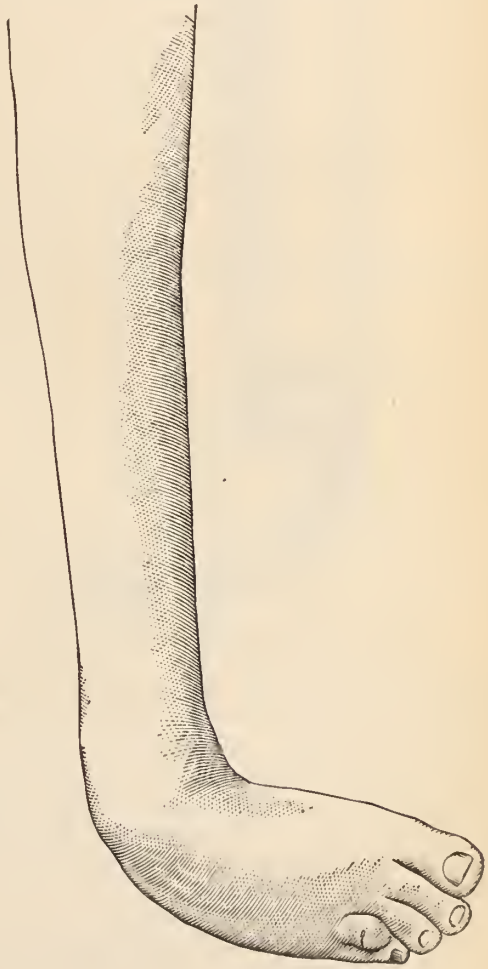

Fig. 5 (Case III).—Before excision of the ankle joint.

The child had been walking about with the convalescent plaster dressing still on, and had probably bruised the limb, or

there was slight exfoliation of bone, causing the pus formation, which, being confined under the dressing, forced the wound open from end to end, instead of discharging, as is usually the case, from a small opening at the point of least resistance. Rapid healing soon took place, and the boy has been perfectly well since. Firm bony union now exists at the site of the knee, and the boy is able to stand without the aid of crutch or support of any kind, and can walk quite well.

The long confinement produced weakness of the left limb, but this is fast gaining strength by use. The action of the hip is pendulum-like, as there is little or no power to flex the thigh. The foot in this patient was in a state of equino-varus, and was straightened during his confinement. If a proper shoe is worn, no operative interference will be needed, as was at first anticipated.

Case III.—*Case of Talipes Equino-Varus from Infantile Paralysis in a Young Woman aged Twenty-five; Complete Correction by Tenotomy and Retentive Apparatus; almost Complete Relapse after Four Years; Excision of Ankle Joint, with Correction of Deformity and Good Locomotion anticipated.*—February 6, 1885, Emma Moore, aged twenty-five, infantile paralysis of right lower extremity, resulting in talipes equino-varus. Four years ago, deformity relieved by tenotomy and retentive apparatus, which was used, until worn out, with comparatively good locomotion; then a rapid return of the deformity. At this second appearance excision of the ankle joint was proposed and readily, under the existing circumstances, consented to, as she was unable to get about at all.

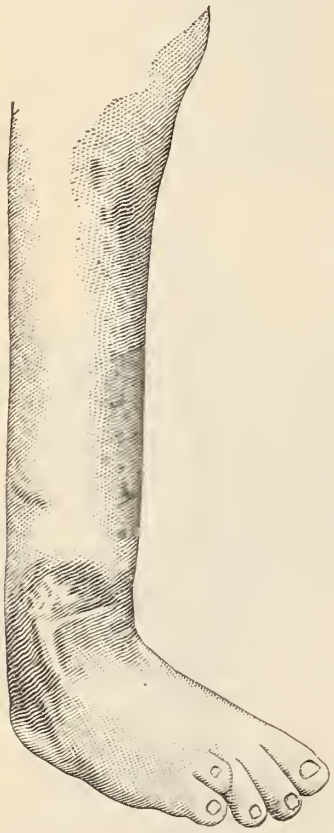

Fig. 6 (Case III).—After excision of the ankle joint.

The patient was placed in the City Hospital of Louisville, and the operation done before the medical classes, February 6, 1885, Dr. J. M. Ray giving ether. After the hæmostatic bandage was applied, a longitudinal incision was made, just anterior to the external malleolus, about three inches in length; the tip of the fibula was snipped off with the bone-pliers to facilitate the breaking of the foot off the tibia, which was then easily accomplished, the articular cartilage being removed by an amputating saw from the tibia and by Hay's saw from the astragalus, there being little or no hæmorrhage, the ligaments acting as tension bands to help hold the bones in apposition, as the hamstrings did in Case II.

An adjustable splint had been made to receive the limb and hold it at rest in the best position. Upon examination of the pieces of bone removed, quite a good deal of what appeared to be fatty degeneration was found in that taken from the tibia, while that from the astragalus appeared firm and healthy.

Prognostications of a fatal result from osteomyelitis and subsequent drain were freely made by my professional brethren present. Notwithstanding the many disadvantages in the way of surroundings and an intercurrent dysentery, she made a good recovery, the only surgical complication being the appearance, about the third week, of a diffuse cellulitis of the anterior part of the calf, yielding readily to treatment.

At the date of obtaining the photograph the patient was in splendid condition, the foot in good position, bony union between the astragalus and tibia secured, and she could bear her weight on this foot, though not allowed to walk on it yet, for fear of irritation and renewed suppuration.

Case IV.—*Subcutaneous Osteotomy of the Femur below the Trochanter for Angular Deformity of Thigh from Hip Disease; the Great Crippling relieved and Good Locomotion obtained.*—June 11, 1884, Homer Colbert, aged nine years, the subject of spinal caries and true hip disease, both long since spontaneously

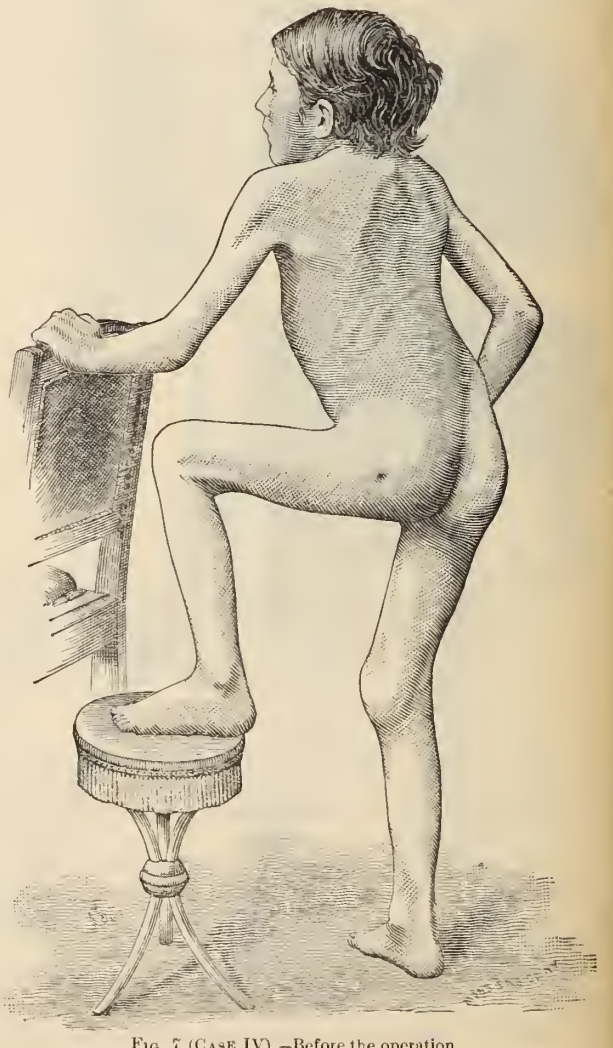

Fig. 7 (Case IV).—Before the operation.

cured, the hip being ankylosed by bone at an angle of less than 90° with the pelvis, the deformity resulting being greater because of the spinal disease in high dorsal region, which took up most of the power of compensation in the lumbar spine.

This boy could stand with difficulty by holding on to his left knee and right hip, but could not walk, his mode of locomotion being on all fours. The patient was an inmate of the Methodist Orphan Home, and ready consent to the operation was obtained; and, on the date mentioned, it was performed in the presence of the visiting physicians of the institution and several other professional friends. The patient was anæsthetized by Dr. Senteny, and turned upon his right side. A block of marble, well padded, was pressed tightly upward on the inner side of the thigh as high as the perinæum would allow. The chisel was entered just below the trochanter, the edge of the blade being in the axis of the limb. It was then sunk by steady pressure to the bone, then turned with the edge across the bone, and driven, with sharp strokes of the mallet, through until its hard substance on the other side was reached and partly entered. The direction was then changed and the same amount of cutting done in several directions until sufficient weakening had been produced to insure our being able to complete the fracture.

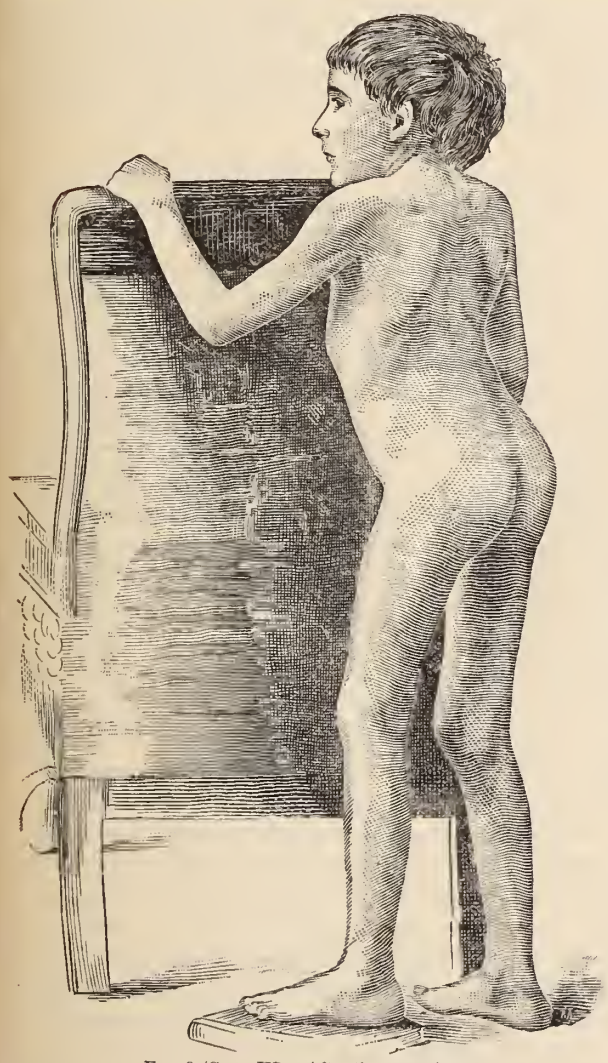

Fig. 8 (Case IV).—After the operation.

Without removing the chisel, the edge of the padded block was placed opposite the chisel and rested on the table, thus acting as a fulcrum at the weakened point. The pelvis being fixed by an assistant, a quick and forcible depression of the lower end of the femur completed the fracture.

The chisel was then removed, and tenotomy of the muscles going to the anterior-superior spinous process of the ilium was done, when, without much difficulty, the limb was brought down and fixed in plaster of Paris, 90° of deformity being overcome. The wounds were dressed with compresses of absorbent cotton and the case was treated as a simple fracture, going on to conclusion without a bad symptom, the boy being able to walk at the end of five weeks. He walks now—when the second photograph is taken—any distance without difficulty, using an elevated shoe to compensate for about one inch and a half shortening of the affected limb.

Case V.—*Deformity of Left Lower Extremity in a Young Man of Seventeen, the Result of Knee-Joint Disease of Many Years' Standing, relieved by Subcutaneous Osteotomy of Lower End of Femur.*—A. B., aged seventeen years, came under observation last November for treatment. There were the history and the evidence locally of an old inflammation of the left knee joint dating back to early childhood. The limb was greatly deformed, and he walked with painful inconvenience. The knee was found with very little motion, flexed at an angle of 135°, the leg being very much rotated in its relationship to the thigh; there was combined with this marked genu valgum. The compensating deformity of the foot being quite great and walking being painful, I was unable to get photographs in this as I did in the other cases.

The procedure of dividing the bone was exactly as in the preceding case, the final steps being much more difficult because of the limited motion at the knee, and the fear that it might be further damaged if too much strained by the use of the leg as a lever; but I succeeded by having the upper part of the bone fixed by a very strong assistant, then, grasping the condyles in both hands, with the application of sudden force downward, using the same fulcrum as before, the fracture was completed and the deformity overcome, after tenotomy of the external ham-string tendon. The limb was dressed in plaster and went on to firm union as a simple fracture.

The young man now walks anywhere without difficulty, and is the possessor, comparatively speaking, of a comely limb, a compensation of one inch and a half being added to the shoe.

June 21, 1885.

HYSTERICAL HEMIANÆSTHESIA, AND ITS IMPORTANCE.

By F. C. FERNALD, M. D. (Harvard),
WASHINGTON, D. C.

Our text-books of medical practice have so little to say on the subject of "hysterical hemianæsthesia" that the majority of practitioners understand neither the full meaning of the term nor its importance as a symptom. The symptom, although most commonly met in young women, is not confined to any age or sex. The left side is far oftener affected than the right. The anæsthesia, which is limited to one side of the body (beginning exactly in the median line) and to its members, and to the special senses of the same side, is, in a strongly marked, typical case, absolute; the sensibility of the skin to touch, pricking, pinching, heat and cold, induced and constant currents, is lost; the faculties of sight, hearing, smell, and taste on the affected side are gone; the accessible mucous membranes also have lost their sensibility; the muscular sense is absent; the skin is cooler and paler than that of the sound side, and bleeds only a little, or not at all, when pricked or slightly cut.

As in other affections, typical cases are not often seen. The variations are numerous; one or more of the special senses may escape entirely or become only slightly impaired; cutaneous sensibility may be merely more or less dulled, or dulled as regards one or another kind of irritation; different areas of skin on the affected side may differ widely in the degree of anæsthesia.

There is no characteristic method of invasion; the trouble may come on suddenly, either with or without loss of consciousness, or it may appear gradually. Its duration may be days, months, or years.

Its departure may be sudden or gradual. There are also motor symptoms, as a rule, and these are generally on the same side as the anæsthesia. They may assume the form of mere weakness, of paralysis, or of rigidity. In cases of this sort the motor disturbance may pass off rapidly, while the sensory disturbance remains; sometimes the two sets of symptoms pass off *pari passu;* at other times both may grow progressively worse.

There are no especial causes of an attack; it has been known to be produced by a strong impression on the emotions, by a fall, and by a jarring or slight injury received in railroad cars. But of most cases there is no assignable cause.

A few rare cases have been reported which presented precisely the same clinical picture as hysterical hemianæsthesia, and of which alcohol, chronic lead-poisoning, and organic brain disease, respectively, were considered the cause. Before going further, it may be well to cite a few illustrative cases.

Case I.—*Hysterical Hemianæsthesia with Hysterical Hemiplegia.*—This patient came to the out-patient nervous clinic of the Massachusetts General Hospital (in which the writer was assistant). E. B., female, thirty-four years old, married, complained of inability to use the right arm and right leg; was able to walk with some difficulty by aid of cane; movements of arm and fingers possible but awkward. This inability to use her arm and leg had been going on for over two years. Previous to this trouble she had pain in right shoulder and arm, which she attributed to strain occasioned by housework, to which she was unaccustomed. After two months of pain she suddenly became hemiplegic. At the time of her visit to the clinic the knee-jerk was normal; no apparent atrophy of muscles on the affected side. By black-board test, the field of vision of right eye limited; color-perception also impaired in same eye; hearing on this side dulled to both air and bone conduction; taste on right side of tongue absent; unable to distinguish the odor of turpentine in right nostril. Her general health was good. With encouragement was able, after a few minutes, to walk without the cane.

Case II.—*Hemianæsthesia from Chronic Lead-poisoning.* (Reported by Sturge, "Brit. Med. Jour.," London, 1878, i, p. 784.)—A man, fifty-two years old, employed in white-lead works, treated in hospital for lead-colic; cured; returned to work; three days later noticed slight weakness in left arm and leg; also observed diminution of sensibility of left half of body. Complained of itching and tingling of left hand and foot; while in hospital noticed dimness of vision in left eye, which has since increased. *Examination:* Grasp of left hand weaker than right; no dragging of left leg, but says it tires quicker than the other; power to resist forced extension or flexion of left leg diminished; no facial paralysis; general sensibility much diminished on left side; same true of face and tongue; in lower part of leg and in foot sensation but slightly dulled; unable to smell with left nostril, right normal; hearing of right ear normal, but with left ear a watch was heard only when placed in contact with that ear. Treated with metal discs; no result. Remained in hospital several weeks unimproved.

Case III.—*Hemianæsthesia Due to Alcohol.* (Reported by the same author, *loc. cit.*)—Man; habitual drinker; had had one epileptiform attack. For two years had paresis of right side. Was admitted to hospital with delirium tremens, and at this time was noticed to have muscular weakness and anæsthesia on right side; amblyopia of right eye; odors not perceived in right nostril; hearing of right ear enfeebled; sense of taste much dulled on right side of tongue. Hemianæsthesia remained stationary for ten days, then began to improve; five weeks after admission, sight equally good on both sides; hearing improved; smell normal; general sensibility still slightly diminished on right side. *Treatment:* Iodide of potassium, gr. xv per diem, with bitter tonic.

Case IV.—*Hemianæsthesia Due to Organic Brain Disease.* (Mentioned by Sturge, *loc. cit.*, but originally reported by Türck, 1859.)—Female, twenty-two years old; died six months after an apoplectic attack followed by hemiplegia and loss of special senses and general sensibility on right side. Autopsy showed a patch of softening lying outside of optic thalamus, which was intact; two thirds of the foot of the corona radiata was involved.

Diagnosis.—Hysterical hemianæsthesia has one striking peculiarity in the fact that the patient is usually unaware of its existence, and that the physician himself is apt to overlook it unless he makes his examination in a thorough and methodical manner. Hence a short description of the proper mode of making the examination may not be out of place. To avoid deception, it is essential that the patient should have his eyes closed during the testing of the cutaneous sensibility, and it is best that he should also not know beforehand what is to be done. The test is made by pricking with pin, by electric brush, by small bottles of water at different temperatures, and by other means that readily suggest themselves. This examination of the skin should be the first test in the examination of the patient, because, if any anæsthesia is found, it gives the key to the affected side, and knowing this we can avoid being deceived while testing the special senses. Always try the special senses of the suspected side first; otherwise the patient may be self-deceived by mistaking what we may call the "after-images" of the impressions that have been made upon the well side for genuine impressions on the affected side.

Both sides of the body should be tested and compared throughout. The field of vision is examined by the black-board test described in Webber's "Nervous Diseases" as follows: "If accuracy is required, it is necessary to use a blackboard with a point of fixation, the patient being placed at a distance of a foot from that point, with one eye covered; a bit of white paper or chalk is then moved from the outside inward until the patient can see it, and a mark is made on the board. This is repeated at short intervals around the central spot until we have marked out roughly the field of vision of the eye." The color test can be made in a similar way by substituting bits of colored paper for the chalk. Conduction of sound through the bone is tested by

a vibrating tuning-fork held between the closed teeth, while both ears are closed; air-conduction is tested by the voice, tuning-fork, or watch, always having the other ear closed.

Nature does not draw sharp lines. Hence it is not always possible to distinguish hysterical from non-hysterical hemianæsthesia. Frequently, however, a doubtful case is cleared up after several examinations and after carefully watching it for a time.

The tendency on the part of general practitioners probably is to ascribe the symptoms to organic brain disease rather than to hysteria. But organic disease is a very rare cause of hemianæsthesia, for only four or five cases with autopsical proof have been reported. The absence of mental disturbance, of persistent cephalalgia, of facial paralysis, of abnormal electrical reaction and of nutritive changes in the muscles, of syphilis or history of it, point to hysteria. Dr. Walton, of Boston, was the first to show that in hysteria the hearing is affected in a peculiar and characteristic way in that bone-conduction is impaired or lost before air-conduction is affected. However, a patient may not present himself soon enough for the physician to observe this. The concentric contraction of the field of vision and loss of color-perception are also characteristic of hysteria. Hemiopia is the usual form of defect in cases where the visual centers are involved by organic disease. Chronic lead-poisoning may be excluded if there be no history of lead, or if no lead be found in the urine either before or after the exhibition of iodide of potassium. The history will also exclude alcohol. Finally, in many of these hysterical cases there is a fluctuation in the symptoms quite characteristic; there may be, for instance, a complete transfer of all the symptoms from one side of the body to the other, or repeated improvements, or even complete recovery, followed by relapses—all utterly inconsistent with the hypothesis of organic brain disease.

Malingering may be suspected, *especially in railroad cases* where there is possibly a question of damages. It is quite inconceivable, however, that a person, often a very ignorant person too, should be able to simulate hysterical hemianæsthesia in its entirety, with the peculiar modifications of vision, hearing, smell, and taste. The amount of injury that may be incurred without pain in these hysterical people is marvelous, and is satisfactory evidence against malingering. Skerritt ("Brit. Med. Jour.," London, 1888) tells of a case of this kind in which a finger-tip was chopped off and a leg broken entirely without pain. The so-called hysterical or nervous temperament is by no means a universal concomitant of hysterical hemianæsthesia. Many of the most marked cases present no other symptoms whatever of hysteria.

Importance of Hysterical Hemianæsthesia.—In all obscure cases of nervous disease one should make it a rule to look for hemianæsthesia, for, if that be found, the other symptoms will most likely be of hysterical origin also. In medico-legal cases, especially railroad cases, we have in this symptom the strongest possible evidence against the theory of shamming, behind which the defendants almost invariably try to intrench themselves.

Treatment.—The treatment is highly unsatisfactory as a rule, often useless. Some patients with hysterical paralysis seem to have lost merely the "knack" of making the muscular contractions essential to certain movements. A case of this kind came to the writer's notice while assistant in the out-patient nervous clinic of the Massachusetts General Hospital. A man with hysterical hemianæsthesia and hysterical hemiplegia, the motor disturbances being especially marked in the leg which was powerless, appeared on crutches, saying that his condition was brought on by a slight shock received in a railroad car. In less than half an hour spent at the clinic he was able to walk across the room unaided by crutches, but awkwardly, however. This result was brought about by having him fix his attention on certain muscles, while these were made to contract by the stimulus of the faradaic current, after which he was induced to imitate the movements by effort of will. He was then told that if he came again on crutches it would be his own fault. He did not give them up, however. He entered suit against the railroad company, but recovered before the trial came off. Massage, tonics, electricity, especially the wire-brush, are sometimes of value. The application of metal discs has been known to cure. A full description of this mode of treatment is to be found in Bartholow's "Therapeutics." Mental and moral influences and *time* are the best curative agents.

THE TREATMENT OF LARYNGEAL PHTHISIS.*

By E. FLETCHER INGALS, M. D., Chicago,
Professor of Laryngology in the Rush Medical College; Professor of Diseases of the Throat and Chest in the Woman's Medical College.

At a meeting of the American Laryngological Association in 1883 I presented a paper on the subject of the treatment of laryngeal phthisis. The views I then held have been but little modified by my subsequent experience, and I can hope to offer very little that is new to those who have read it. However, the malady is one of so distressing a character that it merits constant effort in seeking means for its relief. I, therefore, have yielded to the request of the secretary to present the subject at this time, with the hope of eliciting a discussion in which much may be brought out that will prove mutually advantageous to us and to those who may hereafter come under our care.

In what I have to say I purposely confine myself to a few suggestions concerning treatment alone, ignoring the entire subject of pathology, ætiology, and diagnosis of the disease.

I gave in detail, in my former paper, the history of several cases, in which I endeavored to illustrate the methods which, in my experience, had proved most successful in meeting the following indications, viz.:

1. The relief of pain.
2. The cure of the disease.
3. The prolongation of life, if the disease could not be cured.

* Read before the American Climatological Association, May 28, 1885.

For the relief of pain I have had more satisfactory results from the use of a pigment consisting of morphine, gr. iv; carbolic acid, gr. xxx; tannic acid, gr. xxx; glycerin and water, āā ʒ iv, than from anything else I have ever tried. It will usually benumb the parts for from twelve to thirty-six hours.

In the intervals between the applications of this pigment, sedative powders may be employed with benefit. Sometimes great relief may be obtained by allowing the patient to use the pigment at home in the form of a spray, first diluting it with two or three parts of water, or even employing it in full strength when we find that it is used properly; thus applied, it relieves the pain and checks cough.

In mild cases, a sedative powder—consisting of morphine sulphate, gr. j–ij; benzoin, gr. xx; bismuth subnitrate, gr. xx; iodoform, gr. xx—may be used by the patient, and even in severe cases it will sometimes be found very beneficial. Powders may be applied directly to the larynx by means of a bent tube, or, in cases where the throat is very sensitive, they may be thrown through the nares with an insufflator, providing they are blown in with considerable force at the moment of a deep inspiration. In about half the cases where this method is tried the application to the larynx will be thorough and satisfactory.

For the cure of the disease, in the early stage when there is simple hyperæmia, the ordinary topical applications for chronic laryngitis seem beneficial; and, even later on, we may hope sometimes to check the progress of the disease by the same remedies, thus preventing the distress incident to extensive ulceration and exfoliation of the cartilages.

At the time I prepared my former paper I had hope for much benefit, in the ulcerative stage, from the application of eucalyptol by means of a brush or a spray; but my expectations have not been fulfilled, although I have found it useful in a few cases.

While great reliance is placed on local treatment, the constitutional malady, which is present in most, if not all, of the cases of laryngeal phthisis, should not be neglected. This requires the same treatment as uncomplicated pulmonary consumption, and a cure of the local affection can hardly be hoped for unless the pulmonary disease can be checked, although life may be prolonged by local applications for the relief of pain. In cases where death is inevitable I follow still the general line of treatment already suggested, which was clearly marked out in my former paper, and the results are very satisfactory. Two patients whom I reported cured in 1883 are still well. One, Dr. J. C. G., who was reported as declining in health, died four months afterward from hepatic disease, which caused excessive enlargement of the liver, but he had no return of the laryngeal affection.

Sometimes the epiglottis or the arytæno-epiglottic folds become the seat of the ulcerative process. There is then likely to be so extensive a destruction of the tissues that the glottis can not be properly closed in deglutition. In such cases food and fluids pass into the larynx and give rise to such severe paroxysms of cough or suffocation that patients will abstain from food for days rather than endure the agony sure to follow any attempt to swallow it. Under these conditions topical applications can do very little, unless feeding is carried on through a stomach-tube. In other cases, where the ulceration has not selected these parts or advanced to such a degree, much can be done to prolong life by the use of some local application to benumb the parts and enable the patient to eat with comfort. For these the pigment of morphine, carbolic acid, and tannin has proved most beneficial.

From the new anæsthetic, cocaine hydrochlorate, I hope for good results; but my experience in its use has been so limited that I can not speak with authority. Thus far its cost has prevented thorough experimentation. Applied in a strong solution of from ten to twenty per cent., with a brush or as a spray, directly to the part, it will probably efficiently relieve pain for a few minutes, or for a time sufficiently long to enable the patient to partake of a hurried meal with some degree of comfort. However, the great objection to its use in this manner is that, in most cases, it is impossible for the physician to be in attendance at the right time three times a day.

The addition of the cocaine to the sedative powder already mentioned would doubtless add to its efficiency, and would furnish an anæsthetic which might be applied by the patient either directly to the larynx or, in the manner spoken of, through the nares.

The combination of cocaine, gr. j, with gr. ix of powdered starch I have recommended to be employed in this manner. I have given the powder for home use in but one instance, and then in the proportion of only two per cent. The patient reported that it did no good whatever. Its failure was probably due to the fact that so small a proportion of the drug was used.

Lack of time has compelled me to confine myself in this paper to my own experience; but I hope that what I have said may call out the personal observations of others, which will be far more valuable than anything I could compile on the subject.

Note.—Since the foregoing was written, I have several times employed cocaine hydrochlorate in laryngeal phthisis, but the results have been unsatisfactory in every case, except in reducing the swelling of arytæno-epiglottic folds.

64 State Street, Chicago, *May 23, 1885.*

SOME MINOR POINTS IN THE USE OF THE GALVANO-CAUTERY.*

By HARRISON ALLEN, M. D.,
PHILADELPHIA.

I desire to call attention to a novel means of application of the snare to the removal of hypertrophied tissue and polypoid growths in the nasal chambers. The single feature of interest in the instrument employed is comprised in the facility with which the loop is maintained in a heated condition. The general shape of the instrument is essentially that of the Jarvis snare. For the details and full descrip-

* Read before the American Laryngological Association, June 25 1885.

tion of the instrument, reference is here made to an article, by the writer, in the "Journal of the Franklin Institute," April, 1885, and a second in Pepper's "System of Practical Medicine," vol. iii.

The advantages maintained for the heated wire over the cold wire are as follows: First, the loop, being pressed against a swelling whose base is broad, can be completely imbedded in it. Secondly, the tissue embraced by the loop can be removed with rapidity. Thirdly, the operation is much less painful than the removal of growths with the cold snare. Fourthly, the bleeding is insignificant in amount.

Let me in addition speak of the manner in which an electrode can be manipulated so as to reach with accuracy points which are remote from the nostril, and which can not be readily seen by the operator. A perfectly straight instrument, when thrust directly back through the nose as far as it will go, will reach, as is well known, the vault of the naso-pharynx nearly at the spot at which inspissated mucus is so commonly found. If the platinum-loop of the electrode is bent at its middle to a right angle, and in this shape thrust through the nose, the main axis of the instrument will be found to touch the vault at its anterior curvature, while the deflected portion will reach a point more remote. When in this position, if the electrode is made part of the galvanic circuit, the loop of course becomes heated, and will imbed itself in the mucus, and the mass can subsequently be withdrawn through the nose.

To reach surfaces at the plane of the posterior nares, it is only necessary to withdraw the electrode from its position at the vault until it is seen by means of reflected light to rest upon the surface which it is desired to cauterize. It is always well to remember that the applications can be made without the electrode being secured to the electrode-handle. When the electrode is in position, the free ends of the instrument, which project beyond the nostril, can be lightly touched by the electrode-handle without in any way endangering a change of position on the part of the loop. The slightest motion on the part of the patient will simply break the contact between the electrode and the connecting wires. The method just narrated is especially useful in cauterizing the membrane overlying the posterior surface of the middle turbinated bone.

SURRENDERING TO DISEASE TOO WILLINGLY; LARGE DOSES OF STRYCHNINE.

By G. SPRAGUE, M. D.,
CHICAGO.

The case reported in the issue of the "New York Medical Journal" of June 20th, by A. D. Rockwell, M. D., New York, of chronic myelitis, is one more of the frequently occurring instances where medical men too often yield to discouraging indications, not estimating at their value the usual effects upon young subjects of wisely planned and long-continued treatment in a given direction, this being seconded by the inherent tendencies in young subjects *toward recovery*. Dr. Rockwell says in that report: "Four physicians, including myself, who had become interested in the case, regarded the condition as entirely hopeless." He adds that "the father, in the face of a completely discouraging prognosis, insisted upon unceasing efforts being made," the result being subsequent recovery.

The case was, "Miss B., aged sixteen," while on a Sunday-school excursion, sat upon a wet, cold rock until congestion of the parts adjacent to the point of exposure was produced, this being followed by paralysis, as stated.

To illustrate the principle here contended for, we will make brief mention of a case:

O. L., a book-keeper, aged twenty-two, of sanguine temperament, short stature, and very vigorous physique, feeling slightly indisposed, applied to a young practitioner from a reputable school, who gave the young man a wet pack, a mode of procedure commonly adopted in his practice, as he afterward stated to the writer. The result of the too-long-continued wet pack upon the body and limbs of the young man was—there being no especial elevation of temperature present to meet the shock—to produce congestion of the base of the brain and upper portion of the spinal column, resulting in epileptoid spasms, these recurring at frequent intervals during each day. He passed at once into the hands of another practitioner, who at the end of nine days acknowledged his inability to control the manifestations. The writer was called to the case (two years have now elapsed), finding the violence of the epileptoid spasms increasing in violence. Pulse 115, temperature 102·5°, tongue coated, and bowels not moving. Put the patient upon ½-grain doses of calomel, conjoined with a little aloin, each three hours, and after the fourth dose the bowels commenced to move gently, the evacuations being small and quite like tar in appearance. The bowels were kept gently in action, the movements taking on a healthy character on the third day. A blister was applied upon the upper portion of the spine, 4 × 4 inches. An immediate abatement of the convulsions followed, to be succeeded, very naturally, by total paralysis of the left side, of both motion and sensation. Ten weeks of treatment found him on his feet, and, feeling pretty well, he asked the privilege of going twelve miles out to spend a short time with a friend. I granted this, with the understanding that he was to be immediately brought back to the city upon the first indication of anything being wrong.

But while at his friend's he was seen by an acquaintance from New York city, who said, "Come with me and I will give you a job at book-keeping." He went without advising me of the movement, which would, of course, have been objected to; worked ten days at his books, was hauled to his boarding-house in a hack, with total loss of motion and sensation in the left side, as before. Medical attendance was summoned, and at the end of a week he had the combined aid of three medical men. The result soon was a declaration from the attendants, all concurring, that the case was a hopeless one; that he could never again walk. Upon this decision being given, his friends here sent for him, and he was brought home, the family supposing the case was, as stated, a hopeless one. I stated to the father of the young man that I hardly concurred in that opinion; that I would give him the necessary attention if they would pledge to faithfully second my movements in every particular; that if he was no better in two months, perhaps he would be in four; and if no better in four months, possibly he might be in eight; if not improved in eight months, perhaps at the end of a twelvemonth we might see him on his feet. As before, there was total loss of motion and sensation of left side, with obstinate tendency toward constipation, which condition was carefully watched and attended to. On the principle that we sel-

dom have pronounced outward manifestations without the coexistence of internal organic disease, the treatment was conducted upon this proposition, early in the management planning to place a blister, 3 × 3 inches, each third day, over the upper twelve inches of the spinal column. After the effect of the third blister was obtained there were indications of improvement. After the fourth had been brought to bear the improvement was pronounced. Regarding other means used, mention will be made under the heading that follows. As to the progress made, in four months the young man could walk, with the aid of his staff, by sliding the left foot across the floor. Soon thereafter he was on the street. Within six months he was ready for duty; a portion of last summer kept books for an ice company, from 7 P. M. to 7 A. M., without injury. At this writing he is book-keeper for one of the city ice companies. There is still a tendency to torpidity of the bowels, but no twenty-four hours is permitted to pass without a movement being produced.

Large Doses of Strychnine.—Having before me, in the issue of the "New York Medical Journal" of June 27, 1885, reference in the proceedings of the American Neurological Association to the use of strychnine in large doses, I take this occasion to say that in the case above related strychnine, in solution (I would in no case administer the drug in pill form), was given in $\frac{1}{40}$-grain doses at first, gradually increasing until $\frac{1}{8}$ grain was given three times daily for two months or more, no manifestations being made other than steady improvement in the patient's condition, with final recovery, as stated above. In a case of nicotin poisoning, under my charge during the past four years, with steady improvement, I have given strychnine in $\frac{1}{12}$ to $\frac{1}{15}$-grain doses for weeks together, three times daily, at such times as the pulse ranged from 60 down to 47 a minute.

Book Notices.

The Curability and Treatment of Pulmonary Phthisis. By S. Jaccoud, Professor of Medical Pathology to the Faculty of Paris; Physician to the Larihoisière Hospital, Paris, etc. Translated and Edited by Montagu Lubbock, M. D. (London and Paris), M. R. C. P. (Eng.), Assistant Physician to Charing Cross Hospital and to the Hospital for Sick Children, Great Ormond Street, London. New York: D. Appleton & Co., 1885. Pp. xiii–407. [Price, $4.]

The basis of this book is a series of lectures delivered in Paris by the distinguished author in the months of December, 1880, and January, 1881, and it is written with all the enthusiasm of a Gallic nature as well as with a conviction based upon extensive experience and study. It is a misfortune which the translator realizes, and expresses in his introduction, that no reference should be made to the bearing of Koch's bacillus upon tuberculosis; but the lectures were given more than a year before Koch's discovery. This fact alone renders the author's ideas concerning the pathology of the disease decidedly behind the times. The outline of the work includes not only the subject of treatment, but a preliminary portion on the nature and curability of phthisis, comprising sixty pages. Treatment is discussed under the following methods: (1) The prophylactic; (2) the hygienic, including hydropathy and aërotherapy; (3) the use of drugs; (4) the use of mineral waters, including a residence at suitable watering-places; (5) the climatic. Two distinct clinical forms of the disease are recognized—the inflammatory or pneumonic form, and the chronic or ordinary one (gray granulation, miliary tubercle, etc.); but the author also agrees with Grancher, who considers that from an anatomical standpoint tubercular granulations and pneumonic infiltrations have the same structure. He also believes that tuberculosis is an infectious disease, though he admits his ignorance of the agent which causes the infection, or the exact manner by which infection occurs. He considers that malnutrition is the chief factor in producing phthisis, and that, when upon that an irritative process or actual inflammation of the lung is ingrafted, tubercle results. The division of tuberculosis into hereditary, innate, and acquired might be condensed by dropping the first of these. One of the chief points which are insisted upon is that pulmonary phthisis in all its forms is curable. The existence of cavities and the occurrence of hæmoptysis need not, of themselves, imply a prognosis of a fatal issue, the number of the former and their size, or the number and quantity of the losses of blood, being the important considerations. The principles which are laid down concerning prophylaxis, the hygienic treatment, and treatment by the use of drugs, are sound enough, but we find nothing new or original in them. In the sections upon treatment by mineral waters and a change of climate, however, the richness of the author's experience is manifest. His directions in regard to the various places which he recommends are based upon personal experience from visiting these places, and the data which he has collected concerning altitudes and barometric pressure, prevailing winds and variations of temperature, conditions of soil and moisture, together with the conveniences of the various stations, and the effects produced upon patients in the different stages of the disease, during many years of practice. All these enable him to speak with something like precision in regard to the results of a sojourn at any station which he may recommend. It is a pity that we have not an analogous work for American patients, since, unfortunately, the treatment of pulmonary phthisis under the most favorable considerations is an expensive affair, and the majority of our patients have neither the inclination to take so long a journey nor the ability to bear the expense of a protracted residence at Madeira, Davos, St. Moritz, the Engadine, Algiers, or any other of the European or African resorts. With the great variety of conditions as to soil and climate which our country affords, certainly the field is a rich one for investigation and for a book similar in its bearings to the one under consideration. The translator's work is exceedingly creditable, and we do not recall an obscure passage in the entire book.

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 7, 1885.

THE AMERICAN ACADEMY OF MEDICINE.

THE Academy's recent annual meeting, a brief report of the proceedings of which will be found elsewhere in this issue, was one of unusual significance. This organization has not been much given to scientific work in the past, but has rather occupied itself with matters pertaining to the elevation of the standards of medical education throughout the country. In this respect the meeting held in New York was no exception, but it was notable for a propositiou looking to a radical change in its by-laws—so radical, indeed, as to amount, in case of its adoption, to the complete effacement of the Academy's most striking peculiarity.

Section 2 of Article III of the present by-laws reads as follows:

"The Fellows shall be alumni of respectable institutions of learning, having received therefrom—1. The degree of Bachelor of Arts, or Master of Arts, after a systematic course of study, preparatory and collegiate. 2. The degree of Doctor of Medicine, after a regular course of study, not less than three years, under the direction and instruction of preceptors and professors. 3. When a candidate is an alumnus of a foreign institution not granting the degree of Bachelor of Arts or Master of Arts, a certificate or certificates, which shall be considered as equivalent by the Council and Academy, may be accepted in lieu thereof, provided he shall have subsequently received the degree of Doctor of Medicine. 4. The Fellows shall also have had an experience of three years in the Practice of Medicine, in one or more of its recognized departments, and shall have a good moral and professional character."

We have copied this section punctiliously, preserving the glory of the capital letters, the Teutonic punctuation, and the blunders of phraseology. In view of the Academy's lofty—not to say pedantic—attitude, the temptation is great to touch more pointedly upon these shortcomings, but just now we are not so much concerned with the Academy's literary achievements as with the proposed change in the substance of its by-laws to which we have alluded. The purpose of an amendment, to be acted upon at the next meeting, is to provide for the admission of graduates in medicine, who, although they may be destitute of literary degrees, "have distinguished themselves in medicine and collateral sciences." Here we can not refrain from a passing remark upon the phraseology of the proposed amendment. Why "*and* collateral sciences"? Must future candidates have distinguished themselves both in medicine and in more than one other science? However, we take it for granted that the proponent's intention is to secure eligibility for medical men who have shown a notable proficiency in either strictly medical attainments or any one of the collateral sciences.

We are convinced that the American Academy of Medicine would be taking a wise step by adopting an amendment plainly setting forth what we infer to be the purport of the proposed amendment, and we think the Academy has been fortunate in having a president who was able and willing to present the arguments in favor of such a change so forcibly as was done by Dr. Gihon in his address, our reporter's abstract of which we regret to have been compelled by the pressure upon our space to abbreviate.

Another important amendment was proposed to Section 1 of Article VIII, entitled "Discipline." The section now reads: "The Fellows of the Academy, in their relations with each other and with their fellow-men, *agree to* be governed by the principles *embodied in the present Code of Ethics of the American Medical Association*, and by the Constitution and By-laws of the Academy." We have italicized the words which it is proposed to change. In place of "agree to," the amendment reads *will;* and in place of "embodied in the present Code of Ethics of the American Medical Association," it reads *which actuate educated and upright men in every profession.* This amendment, too, we think the Academy would do well to adopt.

THE MEMORY OF WILLIAM HARVEY.

Two years ago we gave a detailed account of the pious act of the Royal College of Physicians in causing the neglected remains of Harvey to be incased in a fitting sarcophagus of its own providing. But that was only a half-measure, and a further duty yet remains to be performed. In another part of this issue of the journal it will be seen that the Harvey Chapel is still but a portion of a ruin. The parochial church of Hempstead is depicted as in a condition that ought to be remedied at whatever cost. Every consideration of propriety points to the medical profession as the fitting source of the means wherewith the restoration of this sacred edifice—sacred not only from its ecclesiastical character, but from its having been made the resting-place of the mortal remains of one of the greatest men who ever adorned medicine—is to be accomplished.

At the solicitation of the Royal College of Physicians the descendants of Harvey gracefully waived their own privilege of caring for his remains, and the parishioners of Hempstead Church, nobly recognizing the propriety of a universal tribute to Harvey's memory, now with equal grace confess their own inability, unaided, to do adequate justice to the demand, and are willing to share the honor with the medical profession at large.

The physiologists of two continents—and with them all practitioners of medicine in every nation—have daily profited by Harvey's great discovery of the circulation of the blood, to say nothing of his numerous other contributions to the advancement of medical science. That these other contributions are of no mean character is plainly shown by the interest taken in the fac-simile reproduction of their author's manuscript lectures—a work of which also mention is made elsewhere in our present issue. It is, therefore, not with any idea of doing a favor to the people of Hempstead, or even to the profession of

medicine in the mother country, that American physicians will take their proper part in providing the means for restoring the sacred edifice in which Harvey's remains were originally deposited, but with the conviction that it is nothing more than the expression of a just feeling of obligation. We trust, accordingly, to be called upon shortly to record the accession of goodly sums to the fund. Already, since our article was put into type, and before our public announcement is made, we have received a generous contribution, which we shall acknowledge in our next issue, and we do not doubt that at the same time we shall be able to acknowledge a number of others.

MINOR PARAGRAPHS.

THE METRIC SYSTEM.

Whatever may be the absolute merits of the metric system, as applied to physicians' prescriptions, in communities where it has been a part of every man's education, from childhood up, it is evident, as we have several times insisted on, that the attempt to transplant it to America is beset with some practical difficulties that are likely for many years to stand in the way of its adoption. Not the least of these difficulties lies in the fact that the use of the system adds an element of perplexity to acts which in themselves are always more or less fraught with danger—the writing and the compounding of prescriptions. This objection has lately had an illustration that well nigh proved tragical, a Jersey City apothecary having put up a certain number of grammes of a violent poison, instead of the same number of centigrammes, and having expressed the opinion that his error was in part due to the confusing effect of the metric system.

POISONOUS CAVIAR.

At a meeting of a Russian medical society, held last spring, a report of which appears in a recent issue of the "Deutsche Medizinal-Zeitung," condensed from the "St. Petersburger medicinische Wochenschrift," Dr. Knoch made some observations in regard to several poisonous varieties of fish, especially three Asiatic species of *Schistothorax* and the Japanese *Tetrodon inermis*. It seems that the roes of these fishes retain their poisonous qualities for a long period; in one of Dr. Knoch's experiments, a portion of roe that had been preserved in alcohol for six months was given to a mouse to eat, with the effect of killing the mouse within half an hour. The symptoms of the poisoning consist of vomiting, purging, syncope, tenesmus, cramps, and dilatation of the pupil, followed by collapse and death. Apparently there is no guarantee that the roes of these poisonous fishes may not find their way to the consumers of caviar in the ordinary course of trade.

HARVEY'S MANUSCRIPT LECTURES.

We learn from the "Medical Times and Gazette" that the Harvey manuscript lectures are soon to be published in the form of a photographic reproduction of the author's handwriting, interleaved with a transcript in type. It is said that the photographic work has been so successful that many of the passages are more legible in the fac simile than in the original.

THE NEW HAVEN HOSPITAL.

We regret to learn that the house staff of the hospital has had reason to make some formal complaints to the governing body of the way in which they have been treated. It is an agreeable surprise, however, to find that the Prudential Committee seems, so far as we can judge from the accounts, disposed to right any wrong that may be demonstrated. It is pleasant, too, to be able to record the forbearance and discretion of the house staff in declining to furnish the newspapers with an *ex-parte* statement.

ETHER AS A TIPPLE.

The "British Medical Journal" says that, at a recent discussion on a temperance report made to the Diocesan Synod of Armagh, in Ireland, reference was made by one of the speakers to a practice alleged to exist in various parts of the North of Ireland, that of drinking ether instead of whisky as an intoxicant. In several instances, it was stated, the excessive use of ether had caused insanity. Action was consequently taken looking to legislation to prevent the unrestricted traffic in ether.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 3, 1885:

DISEASES.	Week ending Oct. 27.		Week ending Nov. 3.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	37	8	39	9
Scarlet fever	24	3	34	5
Cerebro-spinal meningitis	0	1	4	5
Measles	7	1	5	1
Diphtheria	46	25	51	18
Small-pox	1	0	2	0

The Health of Massachusetts.—The Secretary of the State Board of Health reports to the Secretary of the National Board of Health for the week ending October 24th: In 109 cities and towns, with a population of 1,312,471, there was a total of 363 deaths, of which number 57 were referred to the principal infectious diseases. No deaths were reported from small-pox.

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, October 27th: *Montreal, Canada.*—For the week ending October 28th: 274 deaths from small-pox in the city, and 73 in adjoining municipalities. *Kingston, Canada*, October 23d, and *Toronto, Canada*, October 21st: Free from epidemic diseases. *Havana, Cuba.*—For the week ending October 22d: 25 cases and 12 deaths from yellow fever. *Matanzas, Cuba*, October 21st, *Nassau, N. P.*, October 17th, *Cape Haytien, Hayti*, October 17th, and *San Domingo*, October 15th: Free from epidemic diseases. *St. Thomas, D. W. I.*—For the week ending October 13th: 1 death from yellow fever, being that of a passenger from St. Johns. *Acapulco, Mexico.*—October 11th: Pernicious fever still prevalent, though the general health of the city is improving. *La Guayra, Venezuela.*—October 17th: City healthy. Reports from *Caracas* still unfavorable. Yellow fever prevalent. *Rio de Janeiro, Brazil.*—For the month of August: 14 deaths from yellow fever. *London, England.*—For the week ending October 10th: 3 deaths from small-pox, including one which occurred in the hospital-ship outside the registration district. The disease is steadily declining. *Paris, France.*—For the week ending October 17th: 5 deaths from small-pox. *Bordeaux, France.*—For the week ending October 10th: 2 deaths from small-pox. During the month of September there were 14 deaths from this disease. *Rheims, France.*—For the week ending October 16th: 2 deaths from small-pox. *Cadiz, Spain.*—For the week ending October 10th: 30 deaths from cholera. *Gibraltar, Spain.*—For the week end-

ing October 11th: 5 cases and 2 deaths from cholera. Communication with cholera-infected districts is unrestricted. *Genoa, Italy.*—For the week ending October 11th: 5 cases and 3 deaths from small-pox. *Venice, Italy.*—For the week ending October 3d: 10 deaths from small-pox. *Riga, Russia.*—During the month of July there were 2 deaths from small-pox. *St. Petersburg, Russia.*—For the week ending October 3d: 2 deaths from small-pox. *Warsaw, Russia.*—For the week ending October 3d: 4 deaths from small-pox. *Calcutta, India.*—For the week ending September 19th: 6 deaths from cholera. *Colombo, Ceylon.*—From August 22d to September 12th: 22 cases and 12 deaths from cholera, and 2 cases of small-pox. *Marseilles, France.*—No deaths reported since October 4th, and clean bills of health are now issued to vessels clearing from the port. In Italy, from September 23d to 27th, there were 690 cases and 382 deaths from cholera. In Spain, from March 4th to September 27th, inclusive, there were 267,689 cases and 98,929 deaths from cholera.

Cremation and the New York Health Department.—It is stated that the sanitary officials of New York do not feel authorized to issue permits for cremation until after certain necessary modifications of the provisions of the Sanitary Code have been made. In the mean time a number of bodies are said to be awaiting cremation, being now stored in vaults in various cemeteries.

The New York Medical Missionary Society.—The Training Institute and Home, at No. 118 East Forty-fifth Street, was dedicated on Wednesday evening.

The Tyndall Foundation.—In accordance with the plan which we alluded to some months since, the proceeds of Professor Tyndall's lectures in this country have been divided between Columbia College, Yale College, and the University of Pennsylvania, for the foundation of scholarships in physics. The sum allotted to Columbia College amounts to $10,800, and the Trustees guarantee that the annual income shall not be less than $648. The recipient of the income is to be appointed annually, but may be reappointed from year to year.

Cincinnati College of Medicine and Surgery.—Dr. Charles E. Caldwell has been elected to fill the vacant lectureship on general pathology.

The "Eastern Medical Journal."—We understand that Dr. C. E. Nelson, of New York, has severed his connection with the journal mentioned.

Personal Items.—Medical Director Philip Landsdale was among the passengers of the steamship Belgenland, which sailed for Antwerp last Saturday.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 25 to October 31, 1885:*

Huntington, D. L., Major and Surgeon, U. S. Army. Detailed on board to inspect Army and Navy Hospital buildings at Hot Springs, Ark. S. O. 245, A. G. O., October 24, 1885.

McElderry, Henry, Major and Surgeon. Granted leave of absence for four months from November 1, 1885. S. O. 246, A. G. O., October 26, 1885.

Patzki, J. H., Captain and Assistant Surgeon. Appointed member of board to meet at Forts Jackson and St. Philip, La., on November 5, 1885, to select a site for the new quarters for the ordnance sergeants at those posts. S. O. 230, Department of the East, October 28, 1885.

Tomey, G. H., Captain and Assistant Surgeon. Granted leave of absence for two months, to take effect after the return from leave of absence of Surgeon J. C. Baily (Major). S. O. 87, Division of the Atlantic, October 24, 1885.

Barrows, C. C., First Lieutenant and Assistant Surgeon. In addition to his other duties, to take temporary charge of office of the medical director, Department of Arizona. S. O. 102, Department of Arizona, October 17, 1885.

Ewing, C. B., First Lieutenant and Assistant Surgeon (Fort Leavenworth, Kan.). To accompany congressional committee, of which Hon. W. S. Holman is chairman, in its visit and inspection through Indian Territory. S. O. 160, Department of the Missouri, October 23, 1885.

Ives, F. J., First Lieutenant and Assistant Surgeon. Relieved from temporary duty at Fort Laramie, Wyo., and ordered to Fort D. A. Russell, Wyo. S. O. 106, Department of the Platte, October 22, 1885.

Morris, E. R., First Lieutenant and Assistant Surgeon (recently appointed). Assigned to duty at Fort Bayard, N. M. He will continue on detached service under orders of district commander. S. O. 160, Department of the Missouri, October 23, 1885.

Marine-Hospital Service. — *Official List of Changes of Stations and Duties of Medical Officers of the United States Marine-Hospital Service, for the week ended October 31, 1885.*

Austin, H. W., Surgeon. To proceed to Portland, Maine, on special duty. October 31, 1885.

Carter, H. R., Passed Assistant Surgeon. When relieved, to proceed to New Orleans, La., and assume charge of the service. October 27, 1885.

Battle, K. P., Assistant Surgeon. Granted leave of absence for thirty days. October 27, 1885.

Williams, L. L., Assistant Surgeon. To proceed to Chicago, Ill., for temporary duty. October 28, 1885.

Society Meetings for the Coming Week:

Monday, *November 9th:* New York Ophthalmological Society (private); New York Academy of Medicine (Section in Surgery); New York Medico-Historical Society (private); New York Academy of Sciences (Section in Chemistry and Technology); Boston Society for Medical Improvement; Gynæcological Society of Boston; Burlington, Vt., Medical and Surgical Club (annual); Norwalk, Conn., Medical Society (private).

Tuesday, *November 10th:* New York Medical Union (private); New York Surgical Society; Medical Society of the County of Rensselaer, N. Y.; Newark (private) and Trenton (private), N. J., Medical Associations; Medical Society of Camden County, N. J. (semi-annual—Camden); Norfolk, Mass., District Medical Society (Hyde Park).

Wednesday, *November 11th:* New York Pathological Society; American Microscopical Society of the City of New York; Medico-Legal Society; Medical Society of the County of Cayuga, N. Y.; Pittsfield, Mass., Medical Association (private); Philadelphia County Medical Society (conversational); Worcester, Mass., District Medical Society (Worcester).

Thursday, *November 12th:* Harlem Medical Association of the City of New York; Society of Medical Jurisprudence and State Medicine; Brooklyn Pathological Society; New York Physicians' Mutual Aid Association (annual, in the Hall of the New York Academy of Medicine, 12 W. Thirty-first Street, at 4 P. M.); South Boston, Mass., Medical Club (private—annual); Pathological Society of Philadelphia.

Friday, *November 13th:* Yorkville Medical Association (private); Medical Society of the Town of Saugerties, N. Y.

Saturday, *November 14th:* Obstetrical Society of Boston (private).

Letters to the Editor.

PRIZE ESSAYS ON DISINFECTANTS.

Brooklyn, *October 26, 1885.*

To the Editor of the New York Medical Journal:

Sir: Inclosed you will please find a verbatim copy of a letter from Dr. Henry B. Baker, in answer to my letter on "Prize Essays on Disinfectants," appearing in the "Journal" of October 17, 1885.

Very respectfully yours,

A. H. P. Leuf.

[*Dr. Baker to Dr. Leuf.*]

"Lansing, Mich., *October 22, 1885.*

"A. H. P. Leuf,

"*199 Dean St., Brooklyn, N. Y.*

"Dear Sir: Accept my thanks for a copy of 'New York Medical Journal,' October 17, 1885, containing your article, 'Prize Essays on Disinfectants.'

"I think you are quite right; and, if I understand the subject, I agree with you entirely.

"This is the first information I have received of the *final* action by the committee; but after I had voted on the subject I was informed that the two other members of the committee had voted as represented in your letter, so I presume you are correct. I immediately protested as vigorously as possible, and have not seen or heard anything further on the subject until I received your article to-day.

"Very respectfully,

"Henry B. Baker.

"You are at liberty to make such use of this as you choose.

"H. B. B."

DIELECTROLYSIS.

10 West Thirty-fifth Street, New York, *November 1, 1885.*

To the Editor of the New York Medical Journal:

Sir: As you correctly state in your editorial, the "dielectrolytic" method is by no means new. I gave the matter a pretty careful examination some ten or twelve years ago. In the experiments then made I used two glass tubes, closed at one end and filled with platinum wires, for conducting the current. One of the tubes was filled with solution of iodide of potassium and the other with thin starch-water. The open ends of the tubes were then closed with gold-beater's skin. If these tubes be now connected with the poles of a galvanic battery (15 to 20 cells) and applied on each side of the arm, in a few moments the starch-water will become blue, showing that a portion of the iodine has left the tube which contained it, traversed the tissues, and appeared in the starch-water tube. The starch tube should be connected with the positive pole of the battery.

Applying this clinically, I met with absolutely negative results. I know that the late Dr. Beard made some experiments of a like nature, and I fancy that Dr. Rockwell has done so likewise. Yours respectfully,

H. G. Piffard.

COCAINE IN SEASICKNESS.

228 West Thirty-fourth Street, New York, *November 1, 1885.*

To the Editor of the New York Medical Journal:

Sir: In the "Medical Journal" of October 31st Dr. Kessler denies the ability of cocaine to palliate or cure seasickness. Well, I am able to verify the statement of Dr. Manassein *in toto.* I made this year two voyages across the Atlantic, crossed the Channel three times, and found cocaine the remedy *par excellence;* but it must be given in repeated doses of a 1-to-500 or a 1-to-1,000 solution. I even found the 1-to-500 solution in delicate persons too strong, and failure followed, whereas the latter acted well. May not Dr. Kessler's failures be ascribed to the large doses, which we still are in the habit of using in too many cases? The bromides are good for nothing, and, till something better turns up, I cling to the 1-to-1,000 solution of cocaine hydrochlorate, a teaspoonful every two hours.

Respectfully,

S. Lilienthal.

Proceedings of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of October 28, 1885.

The President, Dr. John A. Wyeth, in the Chair.

A Cast of the Bladder.—Dr. Louis Waldstein, of the Microscopical Committee, reported that the specimen of exfoliative catarrh of the bladder, presented by Dr. H. J. Boldt at the last meeting, contained but very few, if any, muscular fibers; it consisted of a false membrane with some portions of the mucous surface; its thickness was largely due to œdematous infiltration.

Dr. Boldt remarked that the body had been exhumed some days after burial, and a physician had made an autopsy, but his report had been very incomplete; he had stated, however, that the walls of the bladder were thickened and contracted.

Ulcer of the Duodenum.—Dr. W. M. Carpenter presented specimens for two candidates. The first one showed an ulcer of the duodenum, an inch by an inch and a half in size, situated half an inch below the pyloric orifice.

General Carcinosis.—In the second case the specimens were of more than usual interest, showing extensive carcinomatous degeneration in various organs of the body in a girl thirteen years and six months old. Her father had died of phthisis. It was probable that two cousins of her grandfather had had carcinoma of the breast. The girl had always been very healthy, and a year ago was a vigorous, romping child. About the middle of August she complained of being tired, lost color, and became listless. She suffered no pain at first, but afterward cried out with pain in the region of the spleen. Her appetite was insatiable. On the 8th of September enlargement of the abdomen was first noticed, and from this time the increase in size in the region of the liver was very rapid. The patient complained of agonizing pain, which she always referred to the region of the spleen. She died in August. At the autopsy it was difficult to remove the liver, because of its great size; its weight was twenty pounds. Cancerous nodules of various sizes studded its surface. All of the organs of the body except the lungs contained nodules. The specimen was referred to the Microscopical Committee.

Dr. Waldstein presented a specimen for a candidate, consisting of a malignant or semi-malignant tumor of the great toe, following an injury.

Fibro-Myoma of the Uterus.—Dr. H. Marion-Sims presented a round tumor of the uterus, about five inches in diameter. The patient had been married eighteen years, had given birth to one child, had always been remarkably healthy, and had been regular in menstruation. Three years ago was the commencement of her illness; she complained at that time of dragging and lancinating pain in the hypogastric regions. The speaker first saw her in October, the present month, when he found the depth of the uterus to be four inches, and discovered a movable tumor in the abdomen which he diagnosticated as a

fibroid of the uterus. The patient was extremely fat, and, to remove the tumor, it was necessary to make an abdominal incision nine inches long. She rallied well from the operation, and there were no signs of inflammation about the wound. On the third and fourth days she complained of distress in the abdomen, and vomited a large amount of black fluid, some of which entered the respiratory tract and caused death by suffocation. The autopsy showed no suppuration about the abdominal wound; the organs were not examined.

Plates for the Support of Pedicle Skewers.—Dr. MARION-SIMS also exhibited some vulcanized-rubber plates with grooves for the support of the skewers, which had a tendency to cut into the abdominal wall.

Dr. J. B. HUNTER had prevented the skewers from sinking into the integument by means of flat buttons, but the plates exhibited were preferable as being larger.

AMERICAN ACADEMY OF MEDICINE.

Ninth Annual Meeting, held in New York, Wednesday and Thursday, October 28 and 29, 1885.

The President, Dr. ALBERT L. GIHON, of the Navy, in the Chair.

Wednesday's Proceedings.

The Study of Medicine as a Means of Education was the title of the first paper, read by Dr. ROBERT L. SIBBETT, of Carlisle, Pa., who first referred to the various elements in education, considering time the most important of these. The medical colleges of the United States were not institutions to be proud of. In this country two hundred and nineteen medical colleges had been chartered, of which ninety-three had become extinct, whereas in Canada only fifteen had been chartered, and twelve remained, all regular. A preliminary examination, with graded courses and frequent examinations, was heartily recommended. A protracted course of academic training was necessary for a proper study of medicine. A State medical examining board with full authority to examine all practitioners, irrespective of degrees, would do more to elevate the profession than all other means combined.

Medical Supervision in Student Life.—Dr. CHARLES MCINTIRE, of Easton, Pa., then read a paper, in which he assumed that the times had changed; that modern life made a greater demand upon the time and energies of the individual, to the detriment of his health and development. It was considered impossible to diminish tasks and give more time to rest and recreation. There was no way known to shorten the period of rest, so something should be done for recreation. The plan suggested was the usual one given by students on these subjects. A careful physical examination at the beginning of school-life and a series of graded bodily exercises under medical supervision throughout school-life were recommended. Many appeared to be ignorant of the end to be obtained by a modern gymnasium, so that in colleges the parents of the pupils were afraid that their children would be injured by the gymnasium. But, as the weaklings were the subject of special care and direction, they were the ones least apt to be harmed and most likely to be improved. The end aimed at was to give such tasks as would tend to strengthen the weaker parts.

The Climatic Treatment of Disease, with an Illustration of Western North Carolina as a Health-Resort.—Dr. HENRY O. MAROY, of Boston, read a paper on this subject. The higher Alleghanies in western North Carolina were described at considerable length as offering mountain health-resorts of a character well suited to a variety of diseases. The deductions had been based on a long tour of personal investigation made during the last summer as a sanitary study.

The President's Address: "What is Medicine?"—At the evening session the PRESIDENT read his annual address. He said that the place of the Academy was not to be sought for among the pathological, clinical, sanitary, and other national associations. It antagonized none of these, but sought to cement all into a compact unity. One of the reasons of its slow growth was the restriction of membership to graduates in medicine who had received degrees in letters. As the co-operation of every educated man interested in the objects of the Academy was desirable, the time had come when every limitation to fellowship should be removed except the solitary requirement that the candidate should be in fact, as in title, "learned in medicine," and in all else that this term implied; but he would make it impossible for any one unfit or unworthy to enter, though he came with an armful of diplomas and had subscribed to the most inflexible of codes, and no matter what faculty, society, or institution he might be delegated to represent. A second reason why the Academy had not met with more pronounced sympathy and support was its necessarily hostile attitude to institutions and individuals who defied the principles of its constitution. It encountered a third obstacle in the lukewarmness of its quasi-friends, some damning it with faint praise, others being exuberant in private but chary of public indorsement. Let us ask ourselves the question, "What is medicine?" It was the most profound and ennobling study that could engage the intellect of man. This was not the popular idea, which was that medicine was only something in a box or bottle, that was prescribed by a man or woman who had acquired more or less skill in administering the particular remedy appropriate for each disease. Medicine involved the knowledge of everything that related, however remotely, to the existence of man, his place in nature, his origin, growth, development, preservation, and continuance. The prevention and cure of those abnormal conditions which tended to his destruction were but one chapter in the volume, which, coming near the end, could not be read understandingly without the thorough comprehension and diligent study of all that preceded. Medicine was so far-reaching in its sources and so connected with every other branch of knowledge that he who would begin its study must first have drank deep of the well-spring of human knowledge. Medicine was a science of such proportions that only a well-educated man could master it. Medicine had no need to rear its superstructure on any other foundation than the broad basis of fact. It had been dragged down to the level of commonplace occupations by the dissensions incited by the dogmas of theorists. When all physicians stood on the plane of higher medicine, there would be less tendency to diverge into extremist classes. Was our estimate of medicine visionary, and had we sought the impracticable? Must we silence our voices because few cared to hear, and cease our efforts because the task was difficult? Must we tread the beaten track, lest we offend prejudices, antagonize pecuniary interests, and upset established orders? Not on this account should we hesitate, if the truth was with us. The ethics of medicine rightly denounced fraternity with charlatans and quacks. Was the dishonor less if we degraded a noble profession by admitting to its rights and honors those who were ignorant, illiterate, and incompetent?

Thursday's Proceedings.

Medical Education.—The following resolution was adopted: *Resolved*, That a committee of three be appointed by the president, to report at the next annual meeting, to prepare a statement of the best preliminary education for medical students, and also a statement of the minimum attainments which medical schools should require of students before admitting them to the study of medicine. It was also resolved to appoint a committee of two to report on the requirements for a preliminary

education of the various medical colleges in the United States and in Canada.

Officers for the Ensuing Year were elected as follows: President, Dr. R. Stansbury Sutton, of Pittsburgh, Pa.; Vice-Presidents, Dr. Lewis P. Bush, of Delaware, Dr. S. J. Jones, of Illinois, Dr. R. L. Sibbett, of Pennsylvania, and Dr. F. H. Gerish, of Maine; Secretary and Treasurer, Dr. R. J. Dunglison, of Philadelphia; Assistant Secretary, Dr. Charles McIntire, of Easton, Pa. Pittsburgh was selected as the next place of meeting. The time, the third Tuesday of September, 1886.

Medical Evidence.—Dr. Thomas J. Turner, of the navy, read a paper which had had its origin in his duty in connection with the naval retiring board. The positions of the medical member of the board were that of an ordinary witness, that of an expert witness, and that of a concurrent judge of both the facts and the law. In the first instance the medical officer made a physical diagnosis; in the second place he made a rational diagnosis based upon subjective phenomena; combining these, he arrived at a conclusion. On questions of science, skill, art, and the like, persons instructed on such subject-matters, known in ordinary language as experts, were permitted, from the necessities of the case, to give "matters of opinion" in evidence; and, as to the necessity which permitted the introduction of such opinions, each tribunal determined for itself at the time. Herein the expert differed from the ordinary witness, who testified as to "matters of fact." The boundary-line where ordinary testimony ended and expert testimony began was not always well defined. So far as related to opinions on medical questions, any one at present might be permitted to testify, the question of the special amount of knowledge being left to the jurors to determine. It followed from this that there was no testimony which varied so immensely as so-called expert testimony. It had been decided that a medical opinion might be received as evidence if it was based upon study without practice, or upon practice without study, and it had been ruled that it was not absolutely necessary that one should have either studied or practiced medicine. The term expert testimony was somewhat misleading, and the term "opinion-evidence," as used by Best, was preferable, for opinions might be admitted in evidence by those who could not be classed as experts. The test of the admissibility of opinion-evidence seemed to be this: Had the expert witness any peculiar knowledge or experience not common to the world which rendered his opinion, founded upon such knowledge or experience upon the subject-matter under inquiry, of value to the Court in determining the truth of the matters at issue? The degree of credence given to opinion-evidence should be founded upon the professional skill, the quickness of perception, the powers of discernment, the aptitude, the acquirements, and the education, as well as the experience and observation, of the expert.

A Report on Laws regulating the Practice of Medicine in the United States and Canada, by Dr. Richard J. Dunglison, of Philadelphia, and Dr. Marcy, was read by Dr. Dunglison.

From New York it was reported that the act of 1884 had not been effective in excluding from the profession grossly incompetent and uneducated men.

Health Officers, Ancient and Modern, was the title of a paper by Dr. Benjamin Lee, of Philadelphia. In regard to the organization of boards of health, the first point made was that, in selecting the material, politics, in the bad sense of the term, should be rigidly excluded. Where it was possible to avoid it, the members should not be elected by the people, especially in large cities. Secondly, boards of health should be composed chiefly of physicians, but at least one member should be a man eminent among his fellows for prudence and judgment in trade and commerce, for doctors were proverbially bad business men. Thirdly, as it was desirable that there should be harmony of action and of sentiment between the municipal government and the board of health, there should be a representative of each in the other. Fourthly, it was essential for the practical working of the board that it should employ a paid agent, who should devote as much time as was necessary to inspection and investigation of the sanitary conditions of the locality, and carry into execution the orders of the board. Finally, every member of the board should receive a fair and even generous compensation for his labors.

Micro-organisms and their Relation to Disease was the title of a paper by Dr. Samuel N. Nelson, of Cambridge, Mass.

Observations on the Relation of Bacteria to Certain Puerperal Inflammations was the title of the next paper, by Dr. Ernest W. Cushing, of Boston. He called attention to the great difference between the customs and rules governing the obstetric assistants and students in Berlin and in Vienna. In the former city, every precaution was taken to avoid not only direct infection, but also any possible carrying of germs in the hair or clothing, as if bacteria were freely present in the air. In Vienna, although the possibility was admitted in theory, yet in practice the assistants and students were allowed to be present at autopsies. Obstetric operations and laparotomies were performed before the whole class, without spray, and the chief assistants gave operative courses on the cadaver every afternoon, relying for safety on washing, bathing, and change of clothing. Practically, sepsis arising in the hospital was very rare, and the results obtained by avoiding direct infection through the fingers and instruments were regarded by the speaker as an argument in favor of the view that puerperal fever was not an entity the poison of which was carried about in the air and entered the system through the lungs, etc., but was the result of the invasion and multiplication of bacteria, arising from infection of the uterus or abraded vagina, as a rule, directly from hands, instruments, or applications.

In discussing this paper, Dr. R. Stansbury Sutton, of Pittsburgh, Pa., said that, while there was no question as to the success achieved by the use of antiseptics in general surgery, yet in abdominal surgery the best results so far had been obtained by strict attention to cleanliness without the use of any antiseptic agencies. He agreed with Dr. Cushing that, when the poison entered the abdominal cavity in laparotomy, or the vagina or uterus in puerperal cases, the germs were not carried by the atmosphere, but by the hands, forceps, ligatures, or instruments. So far as abdominal surgery was concerned, he thought that all chemical agents could be discarded, but cleanliness could not be lost sight of.

Dr. Marcy related a case bearing on the introduction of antiseptics into the peritoneal cavity. It was that of a child four years of age, whose abdomen was filled with pus, in which the streptococcus was found. The pus was evacuated and the peritoneal cavity thoroughly washed out with bichloride-of-mercury solution. The patient recovered without a bad symptom.

Medical Licenses and Medical Honors was the title of a paper read by Dr. Edward Jackson, of Philadelphia. A comparison was made between the requirements of the medical colleges of this country when first organized and the requirements of to-day, and a gradual lowering of the standard, with a corresponding decrease in the honor conferred, was noted. The speaker thought it doubtful if any system of State license to pursue any calling should be looked on with favor. If adopted, it must be removed from all possibility of lowering competition, and surrounded by every guarantee of honest enforcement which disinterested examiners and full publicity could give.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of October 1, 1885.

The President, Dr. B. F. Baer, in the Chair;

Dr. W. H. H. Githens, Secretary.

The Different Forms of Paralysis met with in Young Children.—Dr. Wharton Sinkler read a paper on this subject. He said that the form most frequently met was infantile spinal paralysis, or polio-myelitis anterior. This term indicated the pathology of the disease, which was an inflammation of the nerve-cells of the anterior horns of white matter of the spinal cord. This affection might come on at any period of life, but was generally seen in children, and usually at the age of two years. The children were generally strong and apparently healthy, and the paralysis was sudden in its onset. Fully two thirds of the cases he had seen had been attacked in the summer months, hot weather and teething seeming to be predisposing agents. Dr. Barton, of Manchester, Eng., reported that, of fifty-three cases in which he noted the time of onset, twenty-seven occurred in July and August. The attack was preceded by fever of greater or less intensity, with pain in the head and limbs, with general soreness when moved or lifted. After a few days, paralysis more or less complete occurred, but in a few days a regression of the paralysis from some of the affected parts occurred. Sensation was undisturbed. Atrophy of the muscles was soon apparent; in fact, the paralyzed portion stopped growing for a time. The temperature of the affected portion was low and the skin was blue and mottled, but there was no tendency to ulceration, and wounds or scratches healed readily. The skin and tendon reflexes were lowered or abolished in the affected limbs. At first response to the faradaic current was lost, and later on the galvanic current produced but little muscular contraction, except when a powerful current was used. When atrophy had set in the reaction of degeneration was seen. Most of the cases of club-foot were the result of infantile palsy. Deformities of the upper extremities were rare, this disease differing in this respect from cerebral palsies. The exact causes of infantile palsy were unknown. Over-fatigue often preceded an attack; sudden chilling was considered by Seguin to be a frequent cause.

The *prognosis* as to perfect recovery was only moderately good. In many cases the most faithful treatment failed to restore the paralyzed muscles, but in almost every case we could expect more or less improvement.

In the early stages of the paralysis, after the subsidence of the fever, the treatment should consist of mild stimulation to the spine; ergot and small doses of bromide of potassium should be given internally. Later in the disease, iodide of potassium should be given instead of the bromide. When the palsy was established, electricity and massage were the means to be depended upon. They must be persisted in for months or even for years. Internal treatment was of little or no value unless there was some failure in the general health of the child.

Spasmodic paralysis as seen in children was of two varieties—when of primary spinal origin, or when there was a descending degeneration of the cord from a primary cerebral lesion. Sometimes there seemed to be a congenital defect in the motor tracts of both brain and cord. In the spinal variety there was often seen, soon after birth, rigidity of the limbs; at first this was only occasional, but, as the child got older, every effort to move a limb caused muscular rigidity in it. The child did not attempt to walk until three or four years of age. Then, when it was supported under the arms and it tried to stand or to walk, the movements were very peculiar and characteristic. The feet were extended and inverted so that the child rested on the toes. The knees were strongly adducted and locked together so that the legs became entangled. By degrees the child became able to walk with the aid of apparatus or some form of crutch. The hands and arms were often affected and every effort caused muscular rigidity to come on. The mind was unaffected in these cases and the speech might be distinct, although it was often very defective. Sensation was unimpaired and the patella reflex and ankle clonus were exaggerated. There was no wasting of the muscles. By these symptoms we inferred that the disease was localized in the lateral columns; but exactly what was the nature of the lesion we did not know, for no post-mortem examinations had been made in these cases. The cause was unknown. Hamilton found three of seven cases which he had collected were premature births. Adherent and contracted prepuce had been thought by some to be the cause by reflex influence of the spasmodic paralysis, but operation had not given relief. The treatment should consist of massage, galvanism to the spine, ergot, and cod-liver oil. Fluid extract of conium might be given to allay spasm. In some cases great improvement followed this treatment.

Even when we could do no positive good to the limbs, very much could be effected by the aid of apparatus. Properly adjusted braces to the legs would enable a child to walk on crutches or in a Durrach wheel crutch.

There was a form of spasmodic spinal paralysis in which the child was imbecile. In these cases there had probably been congenital defect in cerebral development. The head was small and there was no evidence of intellect; often nystagmus was present.

Paralysis from Pott's Disease.—Paralysis of the lower extremities might result from caries of the spine. The lesion might be either a meningitis or a myelitis. If meningitis alone, there was considerable pain and contraction of the legs. Generally there was a transverse myelitis. The symptoms were numbness and pricking of the legs, with loss of sensation; gradually increasing loss of power with wasting of the muscles; incontinence of fæces with retention or incontinence of urine. Sometimes there were ulcers over the sacrum or on the limbs.

The indications for treatment were evident. An apparatus which would take the weight of the body from the spine was necessary, and was sometimes sufficient of itself. Frequently, however, the application of the actual cautery over the spine produced improvement in the symptoms when an apparatus had done no good. Massage and electricity should be used to restore the atrophied muscles.

Paralysis from rhachitis and diphtheria was seldom complete. The former was often spoken of as the pseudo-palsy of rickets. Negro children, who were very subject to rhachitis in cities, often had rhachitic paralysis. The child at three or four years was unable to walk or stand. Sometimes it had not sufficient muscular development to sit upright. It could move every limb and had no loss of sensation, but had no power. Cod-liver oil and massage brought about the most satisfactory results in these cases. Diphtheritic paralysis usually began in the muscles of the soft palate and pharynx and extended to the extremities. It was generally bilateral and incomplete, but he had seen a case in which it was hemiplegic. It was considered peripheral in character and was believed by some to be connected with the altered condition of the blood consequent on the original attack. Diphtheritic paralysis was rarely fatal and lasted in most cases only a few weeks, although it might continue for months. Strychnia and electricity were the means to be employed, and the case usually responded promptly to these remedies.

Pseudo-hypertrophic paralysis was a rare affection, but was of much interest. The disease belonged almost exclusively to infancy. It was characterized by muscular paralysis with great

increase in the bulk of the muscles. This enlargement was due to fatty deposit, while the muscular tissue proper was atrophied. The affection began with weakness of the legs, a peculiar balancing of the trunk, and separation of the legs in walking. The shoulders were thrown far back in standing and walking. There was great difficulty in getting from the sitting to a standing position. Later in the disease the muscles became wasted and shrunken and the general health began to suffer. Death resulted from implication of the respiratory muscles. The skin was mottled like a piece of Castile-soap. The tendon reflexes were abolished, and electro-muscular contractility was impaired. There was often a greater or less amount of mental weakness. There was no loss of power over the bladder and rectum, and sensation was not affected. Heredity influenced the disease, which was slow in its progress, but the course was steadily downward.

Friedreich's disease was still more rare than the preceding. It was practically locomotor ataxia in childhood. There was evidenced here also a hereditary predisposition, and the female children seemed most liable.

Cerebral Palsies.—Hemiplegia might result from some injury at the time of birth, either from the forceps or from the pressure of a prolonged labor. A child might be born hemiplegic after a perfectly natural and easy labor. Under these circumstances, we must regard the paralysis as the result of imperfect cerebral development. Hemiplegia under these circumstances was generally permanent. The side affected grew less rapidly than the other. The flexors of the arm and hand were usually contracted. The leg became rigid in the act of walking. Convulsion was almost always associated with cerebral paralysis, either immediately preceding the attack or occurring soon after. The convulsive movements were most violent on the side which was subsequently paralyzed. The child would have an idiotic expression and speak indistinctly, but its friends thought it intelligent. The convulsions were liable to return when the child was older and then assume an epileptic form. The walk was peculiar, and was called the spastic gait. The patient plodded along looking as if he were about to pitch forward. The affected limbs were smaller and shorter, the growth of both bone and muscle being affected. In the choreic variety, where the arm was in constant motion, the muscles might become hypertrophied, but the bone remained short.

Prognosis.—As a rule, the prospect of recovery was bad; even if the patient got well, the hemiplegic side remained awkward.

Treatment.—Cod-liver oil and massage, which always relaxes the contracted muscles. The affected limbs should be used as much as possible.

Dr. Harris inquired if Dr. Sinkler had ever observed any hereditary predisposition to convulsions and cerebral paralysis.

Dr. Sinkler replied that the hereditary influence was decided even when no convulsions occurred.

Oophorectomy.—Dr. E. E. Montgomery reported the following case: Mrs. L., of Columbia, Pa., aged thirty-six years, married ten years, pregnant five times; the last, four years ago, was brought to his notice by Dr. A. F. Chase. Her health had been bad since her last confinement. First menstruation at twelve years and a half, regular and very free for one year and a half, when she fell, producing pelvic distress, after which for seven years the flow was very scanty, lasting but one or two days, and accompanied by excruciating pain. She improved somewhat after marriage. Her first conception was followed by so much nausea, vomiting, and anæmia, that her physician advised and induced an abortion.

She was now regular as to time but irregular as to quantity; it was preceded by an excruciating pain for two days and continued until the flow disappeared; she also had severe pain in the head. She was very nervous at all times, but this was much intensified during the period. Pain was more marked in the left inguinal region and down the corresponding limb. Coition and vaginal examination were very painful. The uterus was enlarged and painful, tender on pressure over both ovaries. Local uterine treatment had been kept up during the entire four years with no relief. Trachelorrhaphy had been performed. Ovariotomy was advised. September 19, 1885, she entered Dr. Montgomery's private hospital, and, assisted by Dr. W. H. and Dr. C. B. Warder, and Dr. E. Eshleman, the uterine appendages were removed. The left ovary was composed of a number of cysts, the largest of which ruptured while adhesions were being separated. The right ovary was not enlarged, but it was removed to insure relief. The wound was closed with silk gut and dressed with sublimated gauze and absorbent cotton. There was no shock. The highest temperature reached was 101·6° at midnight of the 20th, and it became normal on the 22d. Sutures were removed on the eighth day and the wound redressed for the first time. It had united throughout, and there was no irritation from the suture. The effect upon her general health remained to be determined.

Supra-vaginal Removal of the Uterus and both Ovaries for Fibroid Tumor.—Dr. Montgomery also reported the following case: Ann U., aged twenty-seven, was brought to him by Dr. T. H. Boysen, of Egg Harbor City, with the following history: Her menses from the beginning occurred every three weeks, and were free an entire week. During the last four years they had occurred every two weeks, and were attended with pain in the pelvis and down the limbs, and severe pressure upon the bladder, causing frequent urination and several times rendering the use of the catheter necessary. Dr. Boysen had diagnosticated fibroid tumor, which Dr. Montgomery's subsequent examination confirmed. The tumor was the size of a child's head, filling up the pelvis and apparently arising from the anterior wall. The examination led him to believe that the bladder was adherent over the anterior surface, and would render the removal of the tumor unsafe. He suggested the removal of the ovaries. She entered his private hospital September 15, 1885, for that purpose. Dr. W. H. Warder, Dr. Boysen, and Dr. Martin assisted, Dr. C. B. Warder and Dr. Staltweather present. An incision three inches long was made, and, finding the tumor free from the bladder, with cervix sufficiently long to serve for a pedicle, the incision was extended to within an inch of the umbilicus above and symphysis below, and the tumor, with some difficulty, withdrawn. In the absence of a Tait's clamp, which had been ordered some days before, the pedicle was constricted by a wire écraseur, and the tumor, with the ovaries, was removed. The pedicle was then transfixed with two steel pins and tied in three sections with strong silk thread. The peritonæum was fastened to the pedicle below the ligatures and the wound closed with silk-gut sutures, the pins holding the stump ontside. The wound was dressed with sublimated gauze and absorbent cotton. The operation was followed by some shock; temperature 97·4°, pulse 104, from which she soon rallied. She complained greatly of pain. A half-grain of morphia had been given by suppository, and three hypodermatic injections of morphia, one quarter of a grain each, were given during the afternoon, before the pain was relieved.

At 3 A. M. of the 24th he was called by the nurse, who reported bleeding from the stump. Three ounces of blood had been lost. By aid of Dr. Warder, a Wells's clamp was applied below the pins, apparently controlling the hæmorrhage; but it recurred later in the day from the angles and from beneath the clamp. By this time the Tait's clamp had arrived, and the patient was etherized, the lower three sutures removed, the pedicle drawn up, the clamp applied so as to control it completely, and the wound again closed. The wound had united throughout.

Temperature reached 100·6° at 9.30 P. M. The highest subsequently, 101·6, was in the afternoon of the 25th, and it became normal on the 28th. Upon removing the dressings on the 27th, some pus welled up about the pedicle. As the skin was irritated, the dead pedicle was cut away until the clamp slipped off. There resulted, of course, considerable retraction of the stump, but the sloughed tissue was nearly cleared away. The patient suffered no pain or discomfort; temperature normal. The tumor was situated in the anterior wall and fundus of the uterus, and projected into the uterine cavity.

Dr. PARISH remarked that removal of the ovaries had given such good results in cases of uterine fibroids, and was comparatively so free from danger, that he would like to hear from Dr. Montgomery his reason for his choice of operation.

Dr. MONTGOMERY replied that the tumor filled the pelvis and pressed upon the bladder and rectum, causing great and constant distress. As diminution of the size of the fibroid tumor was not a certain result of oöphorectomy, and as all the circumstances were in favor of the major operation, he decided upon it as the best one.

Reports on the Progress of Medicine.

OTOLOGY.

By CHARLES STEDMAN BULL, M. D.

The Effect of Sounds upon Diseased and Healthy Ears.—Roosa ("Ztschr. f. Ohrenheilk.") draws the following conclusions from his observations: 1. Many persons, who in quiet places suffer from deafness, hear readily during or in the midst of a loud noise. 2. The disease in such cases is situated in the middle ear, and is of the chronic, non-purulent variety, though it may be an acute catarrh, and even a chronic purulent process with partial loss of the drum-head. 3. The cause of this phenomenon probably depends on an altered action of the ossicula. 4. The acuteness of hearing of laborers in a boiler-shop steadily diminishes. 5. The disease produced by this occupation lies in the labyrinth or trunk of the acoustic nerve. 6. These patients do not hear better in a noise, but their hearing is better in a quiet place, and improves by absence from the source of injury which causes the deafness. 7. The cases of hardened wax and catarrh of the middle ear occurring in boiler-makers resemble those met with among other laborers; they mask and complicate the original disease known as "boiler-makers' deafness." 8. In disease of the labyrinth or acoustic nerve the tuning-fork C is heard louder and longer by air-conduction than by bone-conduction.

The Production of Artificial Deafness, and its Relations to the Ætiology and Development of Ear Disease.—Cassels (*Ibid.*) formulates three theories as to the ætiology and development of disease of the ears: 1. A certain degree of tension of the drum-head is necessary to a perfect functional act of the drum-head. 2. The essential cause of all disturbances of hearing depends upon an alteration in the normal tension of the drum-head. 3. All pathological symptoms in ear disease are developed in regular succession. As a result of his experiments in the production of artificial deafness, he considers that when three of the ordinary symptoms of a disease of the ears may be produced by an experiment within a few minutes, and in the order of succession in which they appear in the natural way in disease, the assumption is justified that, if this experiment were continued for hours or days, these symptoms would be further developed and might produce complicated tissue changes.

Caries of the Petrous Bone, with Paralysis of the Facial Nerve and Fatal Hæmorrhage from the Carotid.—Moos and Steinbrügge (*Ibid.*), in a report of such a case, call attention to the rapid development of the caries, within a period of four months. There was total destruction of the cells of the mastoid process. They regard it as doubtful if such an extensive sclerosis could develop in so short a time along with the carious process, and think it probably began a year earlier—at the time of an attack of typhus fever from which the patient had suffered.

Perforation of the Mastoid Process.—Hartmann (*Ibid.*) gives the results of this operation in fourteen cases, and lays down rules for its performance. 1. The incision in the skin and the opening in the bone should be made in the line of attachment of the auricle to the bone or immediately behind it. 2. The wound should not be made farther upward than the level of the upper wall of the auditory canal. 3. The wound should be sufficiently large to admit of perfectly seeing the bone and carefully treating it. 4. The wound must be kept open until the bottom has become filled by concentric granulations. 5. All secretions or cholesteatomatous masses must be carefully and thoroughly removed, and the walls of the wound and bony canal must be filled with powdered iodoform.

Pyæmia in Acute Suppurative Inflammation of the Middle Ear.—Hessler ("Arch. f. Ohrenheilk.") here gives the results of five autopsies of cases of suppuration of the middle ear, which he had taken from published reports of cases. In the first case there was acute caries of the walls of the tympanic cavity, but the left transverse sinus was empty. In the second case the transverse sinus contained a pulpy, degenerated, and completely decolorized thrombus, which extended into the bulb of the jugular vein. In the third case there was caries of the walls of the tympanic cavity, with pus between the dura mater and tegmen tympani, but no thrombi in the lateral sinuses. In the fourth case the brain substance and ventricles were normal, and there was no sign of caries in the petrous bone *in situ*. In the fifth case there was no change in the brain and sinuses, but the middle ear was filled with thick, offensive pus. In all these cases the patients had suffered from symptoms of pyæmia. He cites in detail a case of his own, occurring in a boy, aged twelve, in whom the pyæmic symptoms were pronounced, but the boy subsequently recovered. From the results of the autopsies, it seems probable that the pyæmic poison in the blood in affections of the ear may reach the circulation not only by means of the sinuses, but also by phlebitis of the small veins in the bony walls of the tympanum and mastoid antrum.

Gumma of the Auricle.—Hessler (*Ibid.*) reports a very interesting case of this rare disease in a man aged twenty-four. There was partial necrosis of the cartilage of the auricle resulting from an ulcerating gumma, which had existed for several weeks. This suppurated for several days at a time, and then the discharge ceased. The right auricle was very much swollen, bluish in color, and stood out straight from the head. The tissues over the mastoid were markedly swollen. Upon the anti-helix was an ulcer, 3 mm. in diameter, with yellow margin and base, and a dirty serous discharge. The external auditory canal was narrowed, but the glimpse of the drum-membrane that could be obtained through the lumen showed it to be normal. The hearing power was undiminished. The initial lesion had probably occurred four years previously. The case was at first treated by cauterizations with silver nitrate and simple lead-washes, and each application of the caustic was followed by enormous swelling of the auricle. At a later visit, the whole substance of the auricle round the ulcer was found undermined, and the cartilage found necrosed throughout a considerable extent. Large doses of potassium iodide brought about a complete cure in less than two months.

The Temporal Bones of Two Deaf-Mutes.—Moos and Steinbrügge ("Ztschr. f. Ohrenheilk.") here gives the results of a very careful macroscopic and microscopic examination of four temporal bones removed from the bodies of two deaf-mutes. The following conditions were common to the labyrinths of all four bones: 1. The absence of nerves in the lamina spiralis ossea of the first whorl of the cochlea; in the upper whorls of both cochleæ of the second case there were still some nerve-fibers present. 2. The arrest of development and atrophy of the ganglion-cells within the canal of Rosenthal. 3. The defective development and fatty metamorphosis of the organ of Corti. 4. The filling of the ductus cochlearis in one case, and of the scala vestibuli in the other case, with a caseous mass of material intimately by coagulated lymph. 5. The occurrence of hyaline masses in various parts of the membranous labyrinth. In the left labyrinth of the second case there was also found a membranous and osseous coalescence of the tissues of the first portion of the first whorl of the cochlea in the scala tym-

pani; and in the first case the nerve-epithelium and nerves in the left sacculus were wanting.

The Employment of Calomel in the Treatment of Otorrhœa.—Gottstein (*Ibid.*) speaks highly of the local employment of calomel in chronic suppuration of the middle ear; when combined with the mercurie bichloride, he regards it as more valuable and prompt in its action than boric acid. He assumes that when calomel comes in contact with fluids which contain sodium chloride, such as pus, the mercuric bichloride is formed; this has a powerful antiseptic action in itself, and in a state of nascent productiou this action is probably more energetic. He has employed calomel in a large number of cases; has found it absolutely non-irritating to the mucous membrane of the middle ear; it never forms any deposits upon or in the mucous membrane which are difficult of removal, and the results of its action are sometimes surprising. He recommends that the ear should be washed out with a weak sublimate solution (0·1 per cent.); then the ear should be inflated by Politzer's method, so as to drive all secretions into the external auditory canal, and these should be removed by another injection. The canal is to be thoroughly dried with cotton and filled with powdered calomel by means of a powder-blower, and stopped with cotton. This method of treatment may be employed even in the beginning of acute inflammation of the middle ear. By reason of its marked insolubility, it always remains finely pulverized and does not clog the powder-blower. Gottstein regards calomel as a much surer and more powerful antiseptic agent than boric acid. The secretion in these purulent cases diminishes within a few days after the commencement of the calomel treatment, and no adverse symptom has ever been noticed from its employment. In some cases Gottstein has employed a mixture of powdered calomel and common salt, and discovered that this mixture was mildly corrosive. He employed this powder in cases of otorrhœa with extensive perforations and swelling of the mucous membrane of the middle ear. The powder causes a slight pain for a few minutes, and the secretion is temporarily increased. The next day there may be seen a thin, grayish-white slough upon the mucous membrane. When this slough comes away the powder is insufflated again.

The Diagnostic Value of the Relation between Air-conduction and Bone-conduction.—Brunner's investigations upon this subject (*Ibid.*) are of considerable interest and importance, and are given as follows: 1. Under normal conditions the air-conduction overbalances bone-conduction, so that the vibrations of a tuning-fork are heard longer and louder through the air than through the medium of the mastoid process. 2. In pure diseases of the external and middle ear, where the deafness has reached a certain degree, the reverse is the case as regards air- and bone-conduction. 3. Neither theoretical speculation nor clinical observation makes it probable that bone-conductibility may be strengthened or increased by pathological processes in the labyrinth or acoustic nerve. 4. Hence it is proper to infer, from the distinct overbalance of the latter, the existence of a constant disturbance in the sound-conducting apparatus, which, by resonance or hindered sound-exit, favors bone-conduction over air-conduction. It must be remembered, however, that the aurist has often to deal with mixed diseases, in which it is necessary to clearly understand the relations of air-conduction to bone-conduction. One of the questions to determine is whether in nervous deafness the expected overbalance of air-conduction might, by simultaneous anomalies in the sound-conduction (such as impacted cerumen), be changed into an overbalance of bone-conduction, and *vice versa*. Another point for consideration is the possibility that in an affection of the sound-conducting apparatus (such as middle-ear catarrh) the expected overbalance of the bone-conduction might be weakened or entirely abolished by a simultaneous complication in the labyrinth. This leads to the question whether the overbalance of boue-conduction always presupposes a more or less intact perception. In these mixed cases two factors are to be considered: 1, the factor which increases bone-conduction by resonance, which is by no means of equal importance in all affections of the sound-conducting apparatus; and 2, the factor which diminishes the bone-conduction caused by an affection of the nervous apparatus. One source of error which must be remembered and avoided is that the relation between bone-conduction and air-conduction, even in the normal ear, is not the same for all tuning-forks, since low-toned forks are more strongly and readily perceived through bones than the high-toned forks. Brunner thinks that there is no doubt that at the entrance of the cochlea in the lowest whorl the actual or innate power of irritation of the terminal nerve-apparatus is much greater than in the upper whorls.

Miscellany.

Surgical Meteorology.—According to Dr. B. W. Richardson ("Asclepiad"), the time is favorable for operation: *a.* When the barometer is steadily rising. *b.* When the barometer is steadily high. *c.* When the wet-bulb thermometer shows a reading of five degrees lower than the dry-bulb. *d.* When, with a high barometer and a difference of five degrees in the two thermometers, there is a mean temperature at or above 55° F. The time is unfavorable for operation: *a.* When the barometer is steadily falling. *b.* When the barometer is steadily low. *c.* When the wet-bulb thermometer approaches the dry-bulb within two or three degrees. *d.* When, with a low barometrical pressure and approach to unity of reading of the two thermometers, there is a mean temperature above 45° and under 55° F.

The University of Pennsylvania.—The Medical Faculty has issued the following circular:

"The passage of the law of 1881, entitled 'An Act to provide for the registration of all practitioners,' etc., placed the Medical Faculty of the University of Pennsylvania in a very embarrassing position. It had no knowledge that the act was before the Legislature, so that no opportunity was afforded of considering it. Hitherto, with great hesitation, the Faculty has issued certificates as to the genuineness of the diplomas possessed by applicants, and these certificates have been acknowledged by officers of registration. It is, however, evident that, in doing this, the Faculty has not complied with the law which requires it to be 'satisfied as to the qualifications of the applicant,' and it is very doubtful whether the certificates which have been given legally entitle their recipients to registration. During the last few months it has become more and more apparent that the University of Pennsylvania, if it continues to grant certificates as to the genuineness of diplomas, must issue such certificates for the diplomas of all sorts of colleges. The genuineness of the diploma is in no way dependent upon the scientific character of the body issuing it. A diploma is genuine if the body from which it emanates has a legal right to issue such diploma, and, if the law is to be interpreted by the University as requiring its faculty simply to testify as to the genuineness of a diploma, it can make no difference whether such diploma is issued by a regular or irregular college. Further, the gradations between colleges in this country are so close as to make the drawing of lines a task of great difficulty, and the Medical Faculty can not set itself up as a judge between colleges, and say that the diploma of this suffices and that does not. A very serious matter is the fact that these certificates issued by the University are looked upon by persons ignorant of the circumstances—*i. e.*, by the general community—as indorsements of the medical qualifications of their possessor, and as being in some measure tantamount to the diploma of the University. When the ease with which genuine diplomas are obtained in America and the little significance which so many of them have are remembered, it becomes evident that the issue of these certificates by the University is an injustice to its own graduates. The Medical Faculty also feels that the qualifications of applicants can only be determined by examination, and that it is not legally justified in issuing any certificates whatever, unless 'satisfied as to the qualifications of the applicant.' It, of course, believes that no one is qualified to enter upon the practice of medicine who can not pass the examinations required from students of the University. It therefore proposes hereafter to exact such examinations from applicants. In the future, all persons desiring from the University of Pennsylvania the indorsement on the diploma demanded by Section 4, of the Act of 1881, will be required to pass an examination on chemistry, anatomy, physiology, materia medica and therapeutics, pathology and morbid anatomy, practice of medicine, surgery, and on obstetrics; failure in any branch will cause rejection. To compensate for the labor of such examinations, a fee of $30 will be charged."

The Remains of Harvey.—In our issue for November 10, 1883, we published a letter from London, describing the ceremonies connected with the transfer of the remains of William Harvey from the dilapidated leaden envelope in which they had lain for more than two centuries to a sarcophagus provided by the Royal College of Physicians. At the same time, October 18, 1883, the remains were transferred from the vault of the church to the Harvey Chapel above. All was done that was then possible toward providing the remains with a proper resting-place.

HEMPSTEAD CHURCH BEFORE THE ACCIDENT.

There is still left, however, the restoration of the church itself to be accomplished. The church is situated in Hempstead, a small and obscure village in North Essex, where the Harvey family settled. About three years ago the tower fell and reduced the building to a ruin. Its former appearance and its present ruined state are shown in the accompanying views, which are reproduced from the London "Graphic."

It appears that the parishioners are too poor to provide the entire funds needed for the restoration of the church, and a committee of our professional brethren in England have very properly taken in hand the task of raising the necessary amount. Sir Henry Pitman, M. D., Royal College of Physicians, Pall Mall East, London, S. W., who is the treasurer of the committee, has issued a circular briefly setting forth the facts, and stating that "*any* contribution will be thankfully acknowledged."

It is for the purpose of bringing the matter to the attention of American physicians that we have written this notice, and we believe that many of them will be glad to contribute something toward the performance of a duty that the medical profession of the whole world owes to the memory of the discoverer of the circulation. The publishers of this journal will take pleasure in forwarding any contributions that may be sent them to the treasurer of the London committee, and all sums received will be acknowledged in these columns.

THE RUINS OF HEMPSTEAD CHURCH.

The Scope of Laws regulating the Practice of Medicine.—Dr. C. N. Metcalf, the secretary of the Indiana State Board of Health, having addressed a number of queries to the Attorney-General, Mr. Francis T. Hord, in regard to the interpretation which should be put upon some of the provisions of the Medical Act, those queries, together with the Attorney-General's replies, have been printed, and we are indebted to Dr. James Bradwell, of Indianapolis, for a copy of the document, from which we quote as follows:

"Q. 4.—'Does the statute apply to a person who undertakes to cure diseases by manipulating the patient's body, by rubbing, kneading, and pressure?'

"A.—The statute applies to persons desiring to practice medicine, surgery, and obstetries only, and it ought not to be so construed as to cover persons not substantially within its terms. (Smith *vs.* Lane, 24 Hun., 632. Wert *vs.* Clutter, 37 Ohio St., 347–352.) In Wert *vs.* Clutter, *supra*, the Court says: 'This statute was not intended to create a right in any one to practice medicine. It was simply intended to prohibit the exercise of the right (which before was universal) by unqualified persons. The right remains in all persons, except those from whom it is taken away by the statute.' In Bibber *vs.* Simpson (59 Me., 181) suit was instituted for $51 for services rendered the defendant's intestate, at his special request, by the plaintiff as a clairvoyant. It appeared from the plaintiff's testimony that she professed to be a clairvoyant; that when asked to examine the patient she saw the disease and felt as the patient did; that sittings or séances were of different durations, from one quarter to one half of an hour each; that she did not pretend to understand medicine or anatomy; that she was requested by the intestate to visit him and render him professional services, and did so as by the account; that she helped him, but he died from taking cold; acquainted him with the prices, and he agreed to pay them, but never did. Appleton, C. J., in deciding the case, says: 'The services rendered are medical in their character. True, the plaintiff does not call herself a physician, but she visits her sick patients, examines their condition, determines the nature of the disease, and prescribes the remedies deemed by her most appropriate. Whether the plaintiff calls herself a medical clairvoyant, or a clairvoyant physician, or a clear-seeing physician, matters little; assuredly, such services as the plaintiff claims to have rendered purport to be, and are to be deemed, medical, and are within the clear and obvious meaning of R. S., 1871, c. 13, sec. 3, which provides that "no person, except a physician or surgeon, who commenced prior to February 16, 1831, or has received a medical degree at a public medical institution in the United States, or a license from the Maine Medical Association, shall recover any compensation for medical or surgical services, unless previous to such services he had obtained a certificate of good moral character from the municipal officers of the town where he then resided." The plaintiff has not brought

herself within the provisions of this section, and can not maintain this action.' In Smith *vs.* Lane (24 Hun., 632), Daniels, J., says: 'The action was brought to recover the price which it was alleged the defendant agreed to pay the plaintiff for the treatment of himself and wife for certain bodily disabilities. It consisted entirely of manipulations with the hands. It was performed by rubbing, kneading, and pressure. The evidence given by the plaintiff was to the effect that he was employed by the defendant to perform these services for a specific compensation, and that he had performed them until the amount due him was the sum of $149. Upon the close of the case on his part, the referee dismissed the complaint because it appeared that the plaintiff was not a graduate of any medical school, and had no license permitting him to practice either medicine or surgery. The direction was given because of the prohibition contained in Chapter 436 of the laws of 1874, and, as no other reason appeared in the case, or the evidence which was given that would prevent the plaintiff from recovering, and whether this act contains anything subjecting him to such disability, is the only substantial point which requires to be considered in the case. The statute in terms merely declared it to be a misdemeanor for any person to practice medicine or surgery who is not authorized to do so by a license or diploma from some chartered school, State board of medical examiners or medical society, or who shall practice under cover of a medical diploma illegally obtained, and for the purpose of qualifying a person neither licensed nor possessing a diploma of the nature of that mentioned to practice medicine or surgery, it was provided that he should obtain a certificate from the censors of a medical society either in the county, district, or State, in which it should be set forth that he had been found qualified to practice all the branches of the medical art mentioned in it. It appears to be quite manifest that the object of the Legislature in the enactment of this chapter was only for regulating the practice of medicine or surgery, as those terms are usually or generally understood, and, confining them to such significance, it is evident that they would not include the occupation of the plaintiff. The practice of medicine is a pursuit very generally known and understood, and so also is that of surgery. The former includes the application and use of medicines and drugs for the purpose of curing, mitigating, or alleviating bodily disease, while the functions of the latter are limited to manual operations usually performed by surgical instruments or appliances. It was entirely proper for the Legislature by means of this chapter to prescribe the qualifications of the person who might be intrusted with the performance of these very important duties. The health and safety of society could be maintained and protected in no other manner. To allow incompetent or unqualified persons to administer or apply medical agents, or to perform surgical operations, would be highly dangerous to the health as well as the lives of the persons who might be operated upon, and there is reason to believe that lasting and serious injuries as well as the loss of life have been produced by the improper use of medical agents and surgical implements and appliances. It was the purpose and object of the Legislature by this act to prevent a continuance of deleterious practices of this nature, and to confine the uses of medicine and the operations of surgery to a class of persons who, upon examination, should be found competent and qualified to follow their professional pursuits. No such danger could possibly arise from the treatment to which the plaintiff's occupation was confined. While it might be no benefit, it could hardly be possible that it could result in harm or injury, and for that reason no necessity existed for interfering with this pursuit by any action on the part of the Legislature. His system of practice was rather that of nursing than of either medicine or surgery. No bodily disability or diseases could either result from or be aggravated by the applications made by him, and what he did in no just sense either constituted the practice of medicine or surgery. He neither gave nor applied drugs or medicine, nor used surgical instruments.'

"It is my opinion that our statute is susceptible of the same construction expressed in said case of Smith *vs.* Lane, and that our statute does not cover the person embraced by your question, and that he is not required to procure a license."

The Health of the State of New York.—The State Board of Health's "Monthly Bulletin" for September gives the total reported mortality as 6,251, the percentage of infant mortality being 37. In each 1,000 deaths there were 134·22 from diarrhœal diseases, 23·20 from typhoid fever, 141·74 from consumption, and 76 from acute respiratory diseases.

The New York Physicians' Mutual Aid Association will hold its annual meeting on Thursday, the 12th inst., at 4 o'clock P. M., at the hall of the Academy of Medicine. A revision of the by-laws will be proposed by the Board of Trustees, and a full attendance of the members is desired.

THERAPEUTICAL NOTES.

Dover's Powder and its Modifications.—Dr. B. W. Richardson ("Asclepiad"), after giving in brief the history of a case of "septinous pneumonia" (a term which he applies to pneumonia "induced by inhaling some toxic product from a cesspool"), says that in cases of that sort there is no such anodyne, no such soporific febrifuge, as Dover's powder. If he could envy any one as a therapeutist, he says, it would be the old physician who originally had the happy thought of blending astringent opium with relaxant ipecac, and both with a diuretic and laxative. He thinks it is often very good practice to modify Dover's powder by combining the one grain of opium and the one grain of ipecac with other salines than sulphate of potassium. True Dover's powder, he continues, contains the nitrate as well as the sulphate of potassium—four grains of each in ten grains of the compound—and it often seems to him reasonable to revert to this form, nitrate of potassium, in small doses, being a good diuretic. He also often ventures upon other modifications: in acute rheumatic fever he usually substitutes sodium salicylate for the potassium salt; in gout, bicarbonate of sodium; in remittent febrile cases, two grains of quinine with five of sodium salicylate; and in quinsy and other febrile throat affections, chlorate of potassium.

The Therapeutic Value of Chloride of Calcium.—Dr. R. W. Crighton ("Practitioner") considers this salt of special value in the treatment of scrofulous affections of the glands, and thinks it has an alterative action in all forms of the strumous diathesis. He uses the crystallized chloride, as the anhydrous salt forms a turbid solution and has an unpleasant taste. He gives one, two, or three grains at a dose to young children, and rarely over twelve or fifteen to adults. The dose of Coghill's solution (five ounces of the crystallized salt to twelve fluidounces of syrup) varies from five to forty minims, according to age and other circumstances. He always gives it in milk, after meals.

Nitrite of Sodium in Gouty Epilepsy.—Dr. J. M. Granville ("Brit. Med. Jour.") thinks that epilepsy is often of gouty origin, especially in female members of gouty families, and in such cases he has produced highly satisfactory results with the following formula:

Sodium nitrite	36 grains;
Sodium hippurate	3 drachms;
Infusion of serpentaria	to 12 ounces.

Two tablespoonfuls to be taken three times a day, before meals. The author says that the dose of sodium nitrite may be increased by one grain after each fit that occurs after the treatment is begun, until the dose of fifteen grains is reached. The mixture should be taken for three or four months.

The Action of Quinine on the Fœtus.—Vadenuke ("Thèse inaug. de St. Pétersb."; "Arch. de tocol.") arrives at the following conclusions: 1. Quinine taken by the mother passes into the system of the fœtus in the proportion of about one ninth of the whole amount. 2. The largest amount is contained in the fœtus at the end of two hours. 3. The fœtus eliminates it in a little more than forty-eight hours, and the neonatus in seventy-two hours. 4. Large therapeutic doses, given to the mother, do no harm to the fœtus. 5. The same is true of large doses repeated every forty-eight hours. 6. Quinine is not an abortifacient. 7. It may ward off abortion or premature labor when the mother is under the influence of fever, especially of malarial origin.

A Mercurial Soap, made by triturating equal weights of mercury and a perfectly neutral olive-oil-and-potash soap, is highly recommended by Dr. P. Spillmann, of Nancy ("Ann. de dermat. et de syphil."), as a substitute for mercurial ointment. It keeps well, is not irritating, and can be washed off from the skin with simple water.

Lectures and Addresses.

MODERN METHODS OF TREATMENT OF PULMONARY PHTHISIS.

BEING A CLINICAL LECTURE

DELIVERED AT THE BELLEVUE HOSPITAL MEDICAL COLLEGE, OCTOBER 27, 1885.

BY BEVERLEY ROBINSON, M. D.,
CLINICAL PROFESSOR OF MEDICINE.

GENTLEMEN: The subject of my lecture before you today is to me a most interesting one. It is especially attractive because I believe, by the general adoption among practitioners of medicine of the means to be referred to, a positive and great benefit may be afforded to a vast number of individuals who are now sufferers from an otherwise almost hopeless disease. Let me say to you at the beginning of my remarks, so as to avoid any possible misapprehension, that I am of the opinion at the present time, just as much as ever before, that all usual means of treatment in pulmonary phthisis which have been proved to be practically useful are none the less advantageous because something newer and further can be added. By all means advise your phthisical patients to observe strictly well-determined hygienic rules, to breathe, habitually, if possible, a high, dry, pure, equable atmosphere; give them cod-liver oil, as much as they can properly digest and assimilate; let all undue mental and physical fatigue be eliminated, if it may be, from their daily existence; locate them in large, sunny, well-ventilated apartments; see to it that their food and drink are nutritious and suitable—in short, do whatever you can to retard the march of disease in the lungs, or to promote and obtain absolute cure. Admitted, then, that this plain duty is set before us; admitted that what our classical text-books teach is sound doctrine and should be unerringly followed, still may we not go beyond their teachings and try new methods which reason encourages and clinical observation and experience obviously support?

The answer is evident. The three methods, then, to which I call your attention, taken in the rank of what I believe to be their relative importance, are:

1. Increased alimentation.
2. Continuous antiseptic inhalations.
3. Intra-pulmonary injections.

One of the symptoms most to be dreaded in the course of pulmonary phthisis is anorexia. When this condition is insurmountable, the patient's future is well-nigh hopeless. Food must be taken, so as to preserve life. But at times the repugnance to food is so great among phthisical patients that they turn from it in sheer disgust. No matter how temptingly the dish is prepared, there still remains the inability to swallow it. Now, then, how can the appetite be awakened, especially when its complete absence is already feared at an early stage of pulmonary phthisis? Of course, we may and should first try the different vegetable bitters, combined, or not, with an acid or an alkali; but if these fail, and very often they will, despite our best-directed endeavor, what then shall we do?

Under these circumstances, and in view of what my reading and personal experience show me, I now recommend washing out the stomach by means of a soft-rubber tube connected with a funnel. After a very short period—sometimes within a few days from the time daily washing is begun—the patient will gladly say that his appetite is already much improved. Take another instance—that, for example, of a patient whose appetite is not good, it is true, but who, nevertheless, forces himself to eat, and who, within a few minutes or hours after food is taken voluntarily, vomits it up. How are such patients to be treated? As I have said in regard to my first example, by washing out the stomach daily until stomachal tolerance is, at least, acquired for easily assimilable food. Further, there is a class of cases in which the anorexia is only moderate and the power of digestion for food not completely lost. Of course, it is an effort to eat, and there is certainly no desire for food. Besides, soon after food is swallowed the patient suffers from weight or pain in the stomach, acid eructations, or extreme flatulence, which are about equally unpleasant and render the patient unwilling to eat unless forced to do so by his own convictions or the urgent appeals of friends. Manifestly in these instances the patients do not take sufficient food, or do not assimilate it well enough to hold their own, far less to repair the daily damages that are effected by the wasting disease of which they are victims. Here again I counsel daily washing of the stomach. In the beginning I do not advise so-called forced feeding by means of the soft-rubber tube. I believe it is wiser in many instances to wait some days before commencing alimentation in this manner; still there are exceptions. In certain cases, even after repeated washing of the stomach, the patient will be unable to retain food after swallowing it. He may feel that he needs food, and he may be perfectly willing to take it, and yet every time he attempts to swallow even a few mouthfuls the food is almost immediately rejected by an effort of retching or vomiting.

Singular to say, the mere act of swallowing appears sometimes to occasion the subsequent feeling of nausea and vomiting. If we introduce food into the stomach with the stomach-tube, even in tolerably large quantities, the food is retained. And not only is it retained, but it is digested and assimilated, and the patient soon feels better and stronger. And with the repeated administration of food in this manner the appetite returns by degrees and in a relatively short time, and the stomachal digestion continues daily to improve. After the lapse of several weeks, a month or two, or perhaps longer, daily washings of the stomach are no longer necessary. These may be repeated at longer intervals, finally to be stopped altogether. In regard to the forced feeding it is somewhat different. The rule is to super-aliment if possible—to give the patient more than he can possibly crave or desire, to make him digest and assimilate more food than he would be willing to, or indeed could, swallow. Now, this may be accomplished by pouring into his stomach once, twice, or even three times a day milk; milk and eggs; milk, eggs, and beef peptonoids, in smaller or larger quantity. The main indi-

cation is, after all, to *stuff* the patient to his or her utmost capacity, short of causing actual distress or incompetence on the part of the digestive organs. It is, again, a remarkable fact that, within an hour or two after the time when a pint or more of milk, two or three eggs, half to an ounce of beef peptonoids have been poured into the stomach of a phthisical patient, he or she will have quite as good appetite as, if not better than, there would have been if no nutriment had been taken. When this forced alimentation, together with the regular daily meals, has been continued for some days, the patient's weight will commence slowly to increase. And, so far as his general condition is concerned, it will be manifestly improved. While this is true, and although flesh and muscular vigor are both obviously on the increase, the intra-pulmonary condition will remain absolutely stationary. It may also progress slowly or rapidly. It may, fortunately, become retrogressive and markedly improved. An instance of the former kind was fully reported by me last June at a meeting of the American Laryngological Association, and I do not wish at the present time to repeat this history. I have not been able to bring before you to-day a case of pulmonary phthisis in which washing the stomach and forced alimentation are being carried out, although I have two such cases (in women) under my care *now* at St. Luke's Hospital. In place of *cases of phthisis* being thus treated, and in order to show you the ease and effectiveness of the plan of forced alimentation, allow me to present to you this man. The patient, J. P., is forty years old, single, and a cigar-maker. He has suffered for a long while from asthma, that followed a bronchial attack which occurred during the war of the Rebellion. He has had dyspepsia during three years, which has frequently been accompanied by vomiting of very offensive liquids. Occasionally he has felt much depressed, and even ill, from the repetition and severity of these paroxysms. All the food he ate lay like a dead weight on his stomach, or gave him intense pain. His power of digestion seemed completely gone, and he suffered continued misery unless he recurred almost daily to the use of purgative pills. In this case the stomach-tube was first used on October 22, 1885, and the stomach washed out thoroughly with warm water slightly alkalinized by means of borax. After the first washing, twenty-two ounces of milk were poured into the stomach and easily retained. The operation of washing and feeding with the tube has been repeated twice since until to-day (October 27th), and to the milk two or three eggs have been added. Already the patient affirms, as you hear, that he has now no pain in his stomach after eating, that food does not lie as a load in his epigastrium, and his appetite has improved. Yesterday he ate and digested some meat without difficulty, which is the first experience of this kind he has had during several months.

Now, then, what this man states I have heard repeatedly before, and had several like cases under my care at different times. For your benefit I will now show you how easily my patient swallows his tube, how easily his stomach is washed out, and how acceptable milk received into his stomach through the tube appears to be. A word or two before I leave this subject in regard, 1, to the apparatus employed; 2, to the best manner of using it. Simple instruments are often the best, and so it is in this instance. The instrument I show you is, in my opinion, the best one for combined washing and feeding with which I am acquainted. There are several others, invented or modified by different physicians, each one having its special advantage, perhaps, but each somewhat complicated; at all events, none quite so simple as the one here shown, which to all intents is little more than a long rubber flexible tube with a vulcanite funnel at one end. To be more particular, I would add that the stomach-tube is similar, except for *increased caliber* and *length*, to those made by Tiemann or Ford for catheterization of the urethra. This one is twenty-eight inches long and about one third of an inch in diameter. It is connected at its proximal extremity by means of two inches of *glass* tubing with a soft rubber tubing of similar size five feet in length. This latter piece of tubing is terminated by a funnel. The stomach-tube may be dipped into warm water before passing it in order to lubricate its surface, or make its passage easier. It is then introduced in the median line beyond the base of the tongue, and the patient is told to swallow. At each repeated effort of deglutition the catheter is pushed farther on until from eighteen to twenty-one inches are introduced. We are then quite sure the tube has penetrated into the stomach beyond the "eyes" by which the food pours into the stomach. So soon as this is accomplished, we raise the funnel to a suitable height—usually the level of the patient's head is sufficient—and pour into it slowly water of about blood-heat, or a little warmer, with the addition of borax. The proportion of the latter may be one drachm to two quarts of water. When we have poured about a pint of fluid into the stomach, or when the patient himself makes *a sign*, or says that his stomach feels distended, we quickly lower the funnel near the floor while *pinching* the soft tube near the funnel with the index-finger and thumb of the right hand so as to retain fluid in the entire length of the tube. So soon as the funnel is lowered into an empty receiving-vessel on the ground, pressure on the tube is relaxed and the water containing the washings from the stomach is siphoned off. After repeated washings, or until the stomach is quite clean and the water comes away clear, we pour in the alimentary substances in the same manner we did the hot water for washing. In withdrawing the stomach-tube we should do it quite rapidly, in order to avoid possible rejection of the food. We should also pinch the tube near its proximal extremity in withdrawing it so that none of its contents will fall upon the carpet or floor. Of course it is understood that the daily *washing* of the *stomach* should take place in the early morning, or at a time when it is comparatively or entirely free from food; otherwise the tube is liable to be choked up by bits of undigested food. Besides, such pieces may be rejected alongside the tube, and possibly become impacted in the larynx or trachea, causing symptoms of asphyxia. Whenever it is inconvenient to perform the washing at a very early hour in the morning, the patient may be allowed some peptonized milk, and the washing may then be delayed for an hour or two. After a certain number of washings the patient himself may be able to

accomplish this little feat quite as well as the doctor. As regards the *mere* passage of the tube, he frequently learns how to introduce it with greater ease to himself than the physician can command, and, while introducing the tube, is perfectly able to make a passing intelligible remark or two.

We now come to the second part of our lecture, viz., the subject of *Continuous Antiseptic Inhalations.* This, gentlemen, has been a subject which I have studied very attentively during the past two or three years. I have examined many different kinds of oro-nasal inhalers, but I know of none so simple, so cheap, and so effective as the one I have in my hand. These inhalers were originally made in London, and sold by Squire. I imported a large number of them for use at the New York Hospital in the out-patient department, and, within a brief period, finding them so useful, I have requested Mr. Ford, of Caswell, Hazard & Co., to manufacture a lot for sale to the public generally. The inhaler itself is nothing but a simple sheet of light zinc perforated with numerous small holes and bent into a somewhat pyramidal shape of suitable size to cover the nose and mouth. The apex of the pyramid—which is the part of the inhaler farthest separated from the mouth and nares—contains a small sponge, held in place by thread, upon which the inhalant is poured. The inhaler is held fixed before the nose and mouth by two light elastics which go around the ears. I have employed at different times a large number of inhaling fluids and many different combinations. The fluid and combination to which I now give the preference is creasote and alcohol, equal parts, to which I also frequently add a like proportion of spirits of chloroform. This combination is certainly very useful in allaying cough and modifying the quantity and quality of the sputa in pulmonary phthisis. I therefore recommend it very warmly. The alcohol is added to the creasote for the double purpose of diluting it and making it more volatile; the spirits of chloroform are added, in view of the experience of Dr. Cohen, of Philadelphia, to diminish local irritation and excessive cough. The inhaler must not be worn too long at first, nor should too much fluid be poured on the sponge at any single time. In either event, instead of giving relief, disturbance is caused; the throat is rendered more irritable, and the patient complains of increased soreness and tightness in the chest. Properly and judiciously employed, the creasote inhalant relieves symptoms notably, and in the beginning, at least, of pulmonary phthisis is, I believe, a means of decided utility so far as the possible arrest of the disease is concerned. It is important that beechwood creasote be employed. At first the inhaler should be worn ten to fifteen minutes every two or three hours; afterward, it may be worn half an hour or an hour at a time, or even longer. When the length of time is gradually increased, only positive benefit will result. From ten to twenty drops of fluid should be added to the sponge at any one time. If more is added, it will cause undue irritation. The fluid should not be poured on the sponge more than two or three times in twenty-four hours. Precisely the way in which creasote is most useful is perhaps difficult to state. By its antiseptic action it is possibly destructive of bacilli; by its local action and general effect it is certainly of value in combating catarrhal conditions. Where purulent cavities exist it tends to destroy or neutralize putridity. These are certainly sufficiently good reasons for its use without pursuing the inquiry further. At all events, these inhalations do good. The physician notices it and the patient affirms it. In many instances they allay cough better than any cough-mixture, and they are certainly free from the great objection of destroying appetite, as opium and morphine so frequently do.

We now come to the third and last topic of to-day's lecture, and that is, *The Utility of Intra-pulmonary Injections in Pulmonary Phthisis.* I for one, gentlemen, believe they do good. I also believe they rarely do any harm. They may occasion localized pleuritis, slight hæmoptysis, or cutaneous emphysema—but that is about all. They certainly allay cough, diminish the quantity and change the character of the sputa, and, in some remarkable manner, have at times manifest power in lessening the distressing symptom *dyspnœa.* This method of treating lung-cavities was first employed in this country by Professor Pepper in 1874; since that time, and except by Dr. Pepper himself, I am not aware that any one but myself has practiced these injections any considerable number of times. I have now made between forty and fifty intra-pulmonary injections, and am disposed to continue them in favorable cases. Of course it is often a difficult thing to follow up any particular line of treatment in private or hospital practice, on account of the prejudices or fears of patients. Thus it is with intra-pulmonary injections, and in a similar degree, perhaps, with forced alimentation, already fully described. Whenever this little operation can be performed, it is, in reality, a very simple matter.

The point of a fine cannulated needle should be inserted in the first, second, or third intercostal spaces anteriorly, or in the axillary region. While there is no risk in making injections upon or outside of a vertical line passing through the nipple on either side, there is danger in injecting at any measurable distance within this line for fear lest we penetrate the pericardium, or one of the great thoracic vessels. The needle should be inserted from two and a half to three inches. Of course, if considered necessary, the slight pain of the puncture may be annulled by the use of local anæsthesia. I have made use of iodine usually in my injections, and am now employing a solution of the compound tincture of the strength of one part to four parts of distilled water. From ten to twenty minims may be injected upon each occasion, and the injection may be advantageously repeated in four or five days. Previous to the introduction of the needle of the Pravaz syringe the patient fully expands his lungs, and retains the air in them during the few moments it takes to make the injection. Slight or moderate cough, some expectoration, streaked or not with blood, may follow the injection, and for a day or two there may be slight localized pain in the region where the injection was made. Further than these symptoms, little or no reaction accompanies or follows the injections. In many cases, as in that of the man whose chest I have just injected for the *third* time within ten days, there is no reaction whatsoever at the time

of the injection, inasmuch as he does not even cough. I I have told you this patient has a cavity at the right apex.

One of the gentlemen wishes to know how I am assured that the point of my needle has penetrated the cavity. The answer is very simple; by giving a slight movement in different directions to the body of the syringe we can readily appreciate whether or not the point of the needle encounters any resistance, or is perfectly movable in an empty space, or one only partially filled with semi-fluid material. But, presuming for a moment that I can not be always confident that I have struck the cavity, does it matter? Practically, and according to me, no. That is to say, if you fear any bad results simply because the injection has been made into solidified tissue about the cavity. Indeed, I am more and more convinced that the best indication for these injections is in cases where the apices are *solidified* and not *softened*. I am borne out in this belief by my own experience. I have already injected in nearly as many cases of phthisical infiltration at its first stage as at a later period, and I have ordinarily seen apparent benefit result. As to the slight accidents that do occur, they can be easily allayed by an anodyne, external irritation of the chest, or rest in bed for a day or two. Of course, when we inject a cavity we have distinct objects in view, and, if we do not reach the cavity, we fall short of doing what we purposed to do. These objects are mainly to disinfect the sputa and to modify the walls of the cavity so that it will, little by little, tend to close up and cicatrize, and, in producing this result, we shall also expect the amount and character of the secretions from the lung-cavity to be sensibly changed for the better. When we inject solidified lung-tissue, we expect something very different. If there is an underlying inflammatory cause in very many cases of phthisis, and I still believe there is, we shall modify this inflammatory exudation considerably. We shall, perhaps, produce such changes in it as to render it fluid and easier of resorption or expectoration. As to the influence of iodine or other injections on the growth or vitality of bacilli, I have yet no very positive and determined views—any more, indeed, at this moment, than I feel perfectly sure in regard to the real, active rôle of the bacillus itself. Only a few months ago the chorus of the supporters of Koch was somewhat after this fashion:

"What is consumption? The bacillus.
What is the bacillus? Consumption.
But what causes consumption? Why, the bacillus.
But what causes the bacillus? Consumption."

And now I ask, in the words of Professor Loomis, "whether they [these microbes] are the *cause* or the *scavengers* of disease?"

Clinically, of one thing I am quite confident, viz., intrapulmonary injections of iodine benefit phthisical sufferers. Why not, therefore, give them the opportunity of the treatment, and await patiently the auspicious day when even changing theory may be wholly favorable to their use.

In conclusion, let me urge upon you all to earnestly consider the facts brought to your attention in this lecture. It is a subject pregnant with the most vital interest. Our hospitals and dispensaries show a fearful death-rate from phthisis. Ordinary methods of treatment are confessedly disheartening by reason of their very slight influence in arresting the march of a dread disease, when, moreover, the *odds* are, for other and manifest reasons, many against the *poor* sufferers.

I have studied with you a series of topics which makes me more hopeful of what I may be able to do for the arrest or cure of pulmonary phthisis. In this line of research may all of you find renewed courage and conviction. Perhaps some one among my hearers may yet discover the "arcana" of science in its conflict with this destroyer of our fellows.

Original Communications.

PARALYSIS OF THE LARYNX; WITH REPORTS OF THIRTY-TWO CASES.*

By H. A. JOHNSON, M.D., LL.D.,
CHICAGO.

The following cases are presented with the thought that they may be useful in future studies. Only what seemed to be the essential facts have been transcribed from my note-books. I have no theories to suggest, but leave the record for the interpretation of those who may be interested in this class of derangements of the larynx. I have not included cases in which the derangements depended upon tumors, ulceration, and other structural alterations of the organ.

DISTURBANCES DEPENDING UPON HYSTERICAL CONDITIONS.

Case I.—H. B., female, single, aged twenty-four. No change in the form or structure of the larynx. The vocal bands in the cadaveric position. Health in other respects fair, menstruation normal, appetite good. Was put upon iron, strychnine, etc., and advised to live as much as possible in the open air. I also applied the faradaic and galvanic currents, the latter interrupted. None of these measures produced any change in the function of the organ. After several months she went East, and finally to Europe, where she consulted a great number of laryngologists, with always the same suggestion of strychnine, electricity, and tonics.

These were tried with the thought that possibly under new conditions and in more expert hands they might be successful. After visiting California and the southern portions of our own country, she went to Europe again, spending a winter in Egypt. On her return she was under the care of Dr. Hughlings Jackson, of London, who had the good fortune to hear her speak after about five years of silence. During three years of this time she did not even whisper. The cords remained as described till her return from Dr. Jackson. At that time she occasionally spoke aloud, but only a part of the time. Upon examination, I then found that in the effort to phonate the vocal processes were brought together, but there was a triangular opening back of their points—in other words, there was a paralysis of the arytænoids, leaving a space through which the air escaped, making phonation laborious and at times producing complete aphonia. From that time to the present, now several years, there have been periods, for several days and occasion-

* Read before the American Laryngological Association, June 24, 1885.

ally for a week or more, that she could not speak above a whisper. She is and has always been fairly nourished, but of a lymphatic temperament, and is easily fatigued. I have repeatedly examined the larynx during the last few years, and have never found any changes except as above stated.

That this was a case of hysterical aphonia I presume no one will for a moment doubt. The interest consists in the fact that the trouble continued so long and resisted all treatment till seen by Dr. Jackson.

Dr. Jackson's treatment did not in any essential respects differ from that which had already been tried. There could be found no evidence of those perturbations of the uterine or other organs which generally accompany these cases. I have said that I presumed this would be admitted to be a case of hysteria. I use the word not in the strict sense of uterine irritation, but for that class of neuroses generally grouped under this name.

Case II.—Mrs. F., aged thirty, married, has had for the last eighteen months some difficulty in speaking, and for the last four months she has been completely aphonic. There has been occasionally dyspnœa, but this has seemed to be asthmatic rather than due to laryngeal stenosis. She has also been under treatment for some uterine trouble. Examination of the lungs reveals some vesicular emphysema; heart weak, but no murmurs; larynx normal in form and color; vocal cords immovable in the cadaveric position. There were no evidences of central trouble nor of any lesion along the course of the nervous trunks. The patient was sent to me by a gynæcologist with the query as to the reflex nature of the laryngeal difficulty.

Case III.—T. H., aged twenty-three, female, single. Nine months ago she took cold; is now aphonic; is short of breath upon exercise; emaciated. Physical examination of chest reveals no evidence of disease of the lungs or heart. She is emotionally depressed. Menses have not appeared for the last five months. No fever or other derangements to suggest organic troubles elsewhere. Tops of the arytænoid cartilages slightly swollen; no loss of motion of abductors; right cord does not come quite to the median line in the effort to phonate; it is lax, sagging, and hanging away from its fellow. This case seems to me to be a paresis of the right thyro-arytenoid and probably also of the right crico-thyroid, hysterical in origin.

Case IV.—M. C., aged seventeen, female, single. Was never strong. Has always been subject to colds and throat trouble. Had diphtheria four years and a half ago; had suppuration of the lymphatic glands of the neck seven or eight years ago; is now in school, but devoting herself mainly to instrumental music; is fairly nourished, but has dysmenorrhœa and signs of ovarian irritation; no lung or heart trouble.

Upon effort at phonation, the cartilaginous glottis is open; in other respects movement of the parts is normal. Says that she formerly was in the habit of singing, but was obliged to abandon all efforts to sing because, as she expressed it, her "voice rattled." There may be a doubt as to the ætiology of this case. The patient had diphtheria four years and a half before the consultation.

Case V.—A. P., aged twenty-five, female, married. Has been aphonic for the last five months. Was referred to me by a gynæcologist. Has laceration of the cervix; has now an acute inflammation of the pharynx and larynx; the vocal cords are in abduction and immovable. No evidence of any central or local laryngeal lesion to account for the paralysis.

Catarrhal.

Case VI.—E. B., aged sixteen, single. Has several times during the last eighteen months lost her voice, being able to whisper only. This has usually been treated by her physician by local applications of argent. nit., thirty grains to the ounce, and in a few days she has recovered. I find thickening of the mucous membranes above the glottic chink, and in normal efforts at phonation the false vocal bands approximate so as to come in contact, shutting out the view of the true cords. In easy respiration the vocal processes are nearly in contact. There must be some paresis of the abductors. The patient was under the care of a physician in a neighboring city, and I learned that she entirely recovered with no other treatment than that mentioned. The health was in every other respect good. The impairment seemed to be the result of acute catarrh.

Case VII.—J. G., aged thirty-eight, male. Three months ago was taken suddenly with hoarseness after getting wet. Very soon afterward the voice became extinct. This condition has continued to the present time. General health in every other respects good. No history of specific disease.

Vessels of the larynx large. Secretions excessive. Left vocal band in efforts at phonation remains midway between adduction and abduction. Motions of right band normal. The interrupted galvanic current was applied with an immediate improvement. The patient soon passed from my observation. The only cause that seemed probable was a catarrh from the cold.

TYPHOID FEVER.

Case VIII.—M. A., aged twenty-nine, female. Had inflammation of the lungs when a child. At the age of twenty had typhoid fever. Soon afterward the voice began to fail. Was unable to sing. Two years ago became very much frightened by an accident, and for two weeks was completely aphonic. Has been hoarse the most of the time since, except when aphonic for ten weeks about a year ago. For the last few weeks has had pain in the larynx and the left side of the chest, running through to the back. No chest trouble. No uterine or ovarian difficulty.

In efforts at phonation the vocal bands remained lax, allowing the air to be expelled between them without the production of sound. The muscles involved seemed to be the crico-thyroids. A marked improvement took place under treatment by the faradaic current.

Case IX.—B. B. B., male, aged fifty-five. Thirty years ago had typhoid fever. After convalescence, became suddenly hoarse and then aphonic.

This condition continued eighteen months, when he recovered the use of the voice. Since then has had, when fatigued, and especially after speaking for a while, a sense of fatigue, which he locates in the supra-sternal region. When eight years old commenced the use of tobacco. Much of the time for forty years he smoked twenty-five cigars daily. Stopped on account of a heart difficulty. Has now post-nasal catarrh. There is also dysphagia, apparently from want of action of the constrictors. The surfaces of the pharynx are very tolerant to mechanical interference. The patient is well nourished, weighing 180 pounds. The action of the kidneys normal. No lung trouble. No organic heart trouble.

Chronic catarrhal inflammation of the larynx. At time of examination, no derangement of motion.

The case is presented for the reason that the patient had just recovered from typhoid fever when the aphonia occurred, lasting eighteen months. The excessive use of tobacco for so long a time in connection with anæsthesia of the pharynx gives additional interest to the history.

SYPHILIS.

Case X.—M. L., aged forty-two, female, married. Has had for eight years some difficulty in swallowing solid food. Says that six months ago "something broke in the throat." Says

that the matter discharged from the throat at that time was not pus, but a "glairy, transparent fluid; it was like the white of an egg." Since then she has been able to swallow better, but there is now constant dyspnœa. This is especially marked when asleep, or when fatigued, or excited during the day. The difficulty is mainly in inspiration. Expiration is easy. General health is not good. Has a family history of cancer and consumption. There was no evidence of thoracic trouble and no history of specific disease.

Examination revealed paralysis of the abductors of both vocal cords. There were no evidences of disease along the course of the nerve-trunks, so far as I could find. I suggested tracheotomy as a measure of prudence, and ordered pot. iod., with the thought that there might have been a specific intoxication. The subsequent history is unknown to the reporter.

Case XI.—D. M., aged forty-seven, male. Had syphilis eight years ago. Six months ago began to have some trouble with the throat. Voice hoarse, but not lost. Secretions of pharynx and larynx increased. Health in other respects fair.

Chronic inflammation of the mucous surfaces of the larynx. Top of left arytenoid cartilage swollen. Left vocal band near the median line, and does not move upon deep inspiration. Right band normal in movement.

I am not quite sure that this is a case of paralysis; it may be an ankylosis of the cartilage.

Case XII.—E. G., aged forty-six, male. Had syphilis in early life. Has had cough and difficulty of breathing for several years. This difficulty came on gradually. It was more marked when asleep than when awake. The appetite is good. No lung trouble. Heart sounds normal. No disease along the pneumogastrics or recurrents. So far as I can ascertain, there are no secondary or tertiary symptoms of syphilis, unless this laryngeal disorder be of that character.

Examination reveals a bilateral paralysis of the abductors of the vocal bands. During phonation the bands become normally tense, separating slightly at the cessation of the act of speaking. There did not appear to be any mechanical fixation of the arytænoids. The quality of the voice is little, if at all, affected. Soon after the first consultation tracheotomy was performed for the relief of a dangerous dyspnœa which occurred during the night. The patient was put upon constitutional treatment, with the thought that it might be syphilitic in origin. No benefit resulted from these measures, and he has worn a cannula now about four years. I am still inclined to think that the case is specific.

Case XIII.—D. M., aged forty-seven, male; had syphilis eight years ago. Six months ago began to be hoarse. The voice is now rough, but not lost. Health in other respects good.

Secretions of the pharyngeal and laryngeal mucous membranes excessive in quantity. Top of left arytænoid cartilage swollen. Left vocal band near the median line, and does not move upon efforts at phonation or deep inspiration. Right band normal in movements.

It is possible that this is a case of ankylosis of the cartilage. The patient was put upon the use of iodide of potassium.

DISEASE OF CENTRAL ORIGIN.

Case XIV.—M. E. P., aged forty-two, male. Never sick till four months before consultation. While on the plains in western Kansas or eastern Colorado he suddenly became aphonic. There was no cause to which he attributed the loss of the power of speech. After a few weeks he partly, but not entirely, recovered, and this improvement was followed by complete aphonia, which has continued to the time of consultation. General health good. No evidence of any thoracic trouble.

Epiglottis pendulous, omega-shaped. Right vocal band normal in movement. The left is drawn close to lateral wall of larynx, so as to be seen with difficulty as a line in the mucous tissues. Upon efforts at phonation there is not the slightest movement of the band. Under the influence of the interrupted current there was a slight change of position. Surface of larynx hyperæsthetic. Subsequent history of case unknown.

Case XV.—P. D., aged sixty-five, male. Five years ago had an injury from a fall, striking upon the right shoulder. Ten days afterward began to have difficulty in speaking. For three weeks could not make himself understood. Has not been able to speak easily since. Now there is something like stammering. There has never at any time been loss of consciousness, nor is there now any impairment of the intellectual functions. The arm and leg of the right side are weaker than those of the left. No deformity of the face or want of co-ordination. Bowels regular. The urine passes slowly. Has been treated during the last five years by various methods, including the use of electricity. Thinks nothing has done him any good. The appetite is now fair; sleep not good. Has headache every day.

Mucous membrane of the larynx slightly injected; otherwise normal. Movements of the left side of the organ very slight. In efforts to phonate, the right arytænoid cartilage is carried beyond the median line, its apex drawn forward of the apex of the left. The edge of the right band is higher than that of the left, and is also carried beyond the median line.

What is the explanation of the paresis of the right side of the trunk and extremities, and the left side of the larynx?

Case XVI.—V. P., aged thirty-six, male. During the last two years has had at times a dull post-sternal pain. This has not been constant in character. Has never been sick since childhood till the commencement of the present trouble. There is no pain in the throat, nor is there constant dyspnœa, but within the last three months there has been shortness of breath upon taking exercise. Speaks now with difficulty; the voice is rough. Of late there has been slight dysphagia. Within the last few weeks there has been some numbness of the left leg. No perversion of the special senses and no ataxia. In other respects the patient seems well. Physical examination of the chest reveals no lung trouble, and I can find no evidence of aneurysm.

Left vocal cord nearly immovable in the cadaveric position. No other alteration of the organ. At a subsequent examination there was the same condition so far as the motions of the parts were concerned. But there was in addition a marked anæsthesia of the mucous surfaces. The dysphagia was increased, and the laryngeal muscles on the left side did not respond to the faradaic current.

Case XVII.—R. W., aged forty-eight, male. Not strong as a child. Had "brain fever" when twenty-one years old. Never had syphilis. About one year ago began to have dysphagia. It came on suddenly, and gradually increased during the year. Five weeks ago attacked with dysphonia. This also came on suddenly, and has remained without change to the present time. Was subject to headache for several years before the commencement of the present troubles. Not so much since the advent of the dysphagia a year ago. Has, however, frequent attacks of neuralgia of the right side of face and head. No evidence of lung or heart trouble.

Right vocal band immovable near the median line. In other respects the organ is normal. Can see no evidence of any dis-

ease along the course of the nerves. The headache, neuralgia, difficulty of swallowing, with the "brain fever," all point to some central lesion.

Case XVIII.—E. N., aged fifty-four, male. Has had for the last ten years some discomfort in the throat. At times dyspnœa. During the last year the difficulty of breathing has been worse, especially upon taking exercise. Seven months ago had a slight hemiplegia of the right side. Is now able to use the right arm to some extent. The throat trouble is worse since the paralysis. Never had any specific trouble. Had typhoid fever twenty years ago. No thoracic trouble, lungs or heart.

Larynx normal in appearance. Upon effort at deep inspiration there is only a narrow opening between the bands. There is only a very slight movement of the bands in phonation. The paralysis of the abductors is not complete, but nearly so.

COMPRESSION OF THE RECURRENT NERVE.

Case XIX.—O. A., aged twenty-four, male. Has had some cough for last six months. A slight hæmorrhage occurred about two weeks before consultation. Evidently deposits in apex of left lung. There has been for some time impairment of voice. Upon inspection, the left band is restricted in the range of movement. No other signs of laryngeal trouble. No swelling of the cartilages or thickening of the mucous membranes.

The interest of the case consists in the fact of paresis of the left side of the larynx in connection with tubercular deposits in the corresponding lung. It is stated by some authorities that such deposits do, by their pressure upon the recurrent, produce paralysis. I think it must be very rare; but this case seems to justify the proposition.

Case XX.—X. S., aged forty-nine, female. Has been hoarse for two years. In that time has lost twenty pounds in weight. Six months ago had rheumatism. No cough. No fever. Examination of the chest reveals a soft bruit at the outlet of the left ventricle with the first sound. This is propagated into the aorta, and heard with great distinctness in the supra-sternal notch. No evidence of any lung trouble.

Color and appearance of the larynx normal, except that the left band moves only very slightly. It is very near the median line, both in inspiration and in phonation. The right in phonation passes beyond the median line to meet its fellow. There must, I think, be a dilatation of the arch of the aorta, producing pressure upon the left recurrent. Saw the patient several months afterward. Found no material change.

Case XXI.—E. B., male, aged thirty-seven. Has been hoarse for the last five months. Recently has been troubled with cough. General health till commencement of this trouble good. Upon examination of the chest, find aneurysm of the aorta at the superior and left portion of the arch. No lung trouble. Paralysis of the abductors of the left vocal band, which remains in the position of adduction in the median line. Motions of right side perfect.

Query.—Why is not the left band in the cadaveric position?

Case XXII.—H. S., male, aged fifty-one. Had, four years ago, a kick from a horse, producing an injury to the back of the head and the right side of the neck. The wound of the neck was on a level with the fourth ring of the trachea. The cicatrix is well marked, and is close to the trachea. Since the injury he has been hoarse; speaks with difficulty. General health good.

Epiglottis large, wide, erect. Complete paralysis of the right side of the larynx. Left side normal.

Case XXIII.—G. T. L., male, aged forty-eight. In early life was not in good health. Twenty years ago spit blood. For the last three years has had some difficulty in speaking when fatigued. This sometimes produced vertigo. Fourteen months ago had a severe strain of the muscles of the right side of the neck; said at the time that he "had broken his neck." Eight months ago began to experience pain in throat, and more decided difficulty in speaking. The voice is now low in pitch and feeble. No lung or heart disease.

Paralysis of laryngeal abductors of the right side, *the cord remaining in the median line.* Left side normal. Why is the cord not in the cadaveric position? Was there an injury to the pneumogastric or recurrent at the time of the "strain"? There had been some difficulty in speaking before that injury.

Case XXIV.—J. C., male, aged sixty-two. Has had hacking cough for twenty-five years. Became hoarse ten months ago. For the last six months has been aphonic. There is now difficulty in swallowing liquids. They pass into the larynx and produce cough and spasm. Appetite good, bowels regular. Kidneys normal. Emotionally despondent. Percussion note normal. Breath sounds harsh; rude over both apices; more marked in front than in back. Heart sounds normal.

Right vocal band immovable in the cadaveric position. Motions of left normal.

Case XXV.—T. B. K., male, aged forty. Has always enjoyed good health till nine months ago, when he fell upon the right shoulder, upon which, for ten or twelve days, the head was drawn down. He rapidly recovered, however, and was as well as ever, except that when he took cold he had a stiffness of the right shoulder. About five months ago he took a severe cold, and had a hard cough with expectoration of white mucus. He recovered from this, and about six weeks ago was suddenly seized with a violent fit of coughing, and immediately the voice became rough and hoarse. There was difficult inspiration. The difficulty was greater while sleeping than when awake. At times there was spasm, making inspiration very difficult. Never had syphilis. Upon physical examination, the lung and heart sounds were found to be normal.

Complete immobility of the right vocal band in the cadaveric position. Left side normal.

UNCLASSIFIED.

Case XXVI.—L. L., male, aged forty-seven. Ten years ago, while pitching hay on a very hot day, he took cold. Cough was severe at the time, and since then he has frequently had hoarseness and shortness of breath. Now the hoarseness is constant. He attributes it to the "cold" ten years ago. Never had any injury along the course of the laryngeal nerves. No specific history. Is well in every other respect. No lung or heart disease. Slight anæsthesia of the pharynx and larynx.

Left vocal band immobile in the cadaveric position. In efforts at phonation, the top of the right arytænoid cartilage passes in front of the left, and the right band is carried beyond the median line to meet its fellow of the opposite side.

Case XXVII.—M. W., female, aged thirty-two. Has a uterine fibroma. Is now taking ergot. During the last three months has had a cough. Has now some dyspnœa. Is hoarse. Speaks with difficulty. No lung or heart derangement. Slight enlargement of the cervical glands, especially back of the left clavicle.

Paresis of the abductors and adductors of the left vocal band. In deep inspiration and efforts at phonation there is only a very slight movement of the vocal band.

Subsequent history unknown. I am not certain that this is not reflex in its origin, but the enlargement of the

post-clavicular glands on the same side with the affected cord leaves a reasonable doubt.

Case XXVIII.—E. W., male, aged five years. Well till eight months ago, when he had an attack of diarrhœa. Soon after began to be hoarse. About four months before consultation, became completely aphonic. No dyspnœa or cough; now well nourished; complains of no pain nor of any discomfort. Laryngoscopic examination reveals paralysis of the adductors of both sides. Electricity was used, interrupted current, with benefit, before a cure was effected. The case passed out of the knowledge of the writer.

Query.—What was the nature of the affection? There was no cerebral trouble, and I could find no cause of interference with the function of the recurrents. There was nothing except the diarrhœa as an antecedent.

Case XXIX.—A. D. B., male, aged twenty-seven. Phonation has been difficult for the last four years. Health in other respects good. Previous to this, had been in the habit of singing, and had used the voice a great deal. Upon inspection, there was seen, in the act of phonation, a wide space between the vocal cords throughout their entire length, including the vocal processes. No other departure from the normal condition.

Query, Was the trouble the result of the over-straining of the tensors and adductors? The subsequent history is not known.

Case XXX.—F. R. C., male, aged twenty-five. Always well until within the last year, during which he has noticed that he becomes easily fatigued by speaking. It is for this that he asks for advice. Says that he is in every other respect well. No specific history. No lung or heart disease.

A triangular opening in the cartilaginous glottis during phonation. Can find no cause for the difficulty.

Case XXXI.—E. F. D., female, aged thirty-eight. In general good health. Ill two years ago, when she had pneumonia. Since then has been subject to cough. Is now hoarse, and has dyspnœa upon taking exercise. Complains of post-sternal pain. No history of any pelvic trouble. Lung and heart sounds normal.

Upon efforts at phonation there is left a wide triangular opening in the cartilaginous glottis. Membranous glottis normal. No thickening of the inter-cartilaginous tissue. Left ventricular band slightly larger than the right.

Case XXXII.—X. M., female, aged twenty-nine. For the last two years has had cough, with expectoration of moderate quantity of mucus. No hæmorrhage. Appetite fair. Bowels regular. Menses normal. No emaciation. Slight dullness at the left top. Breath sounds rude over the same region. Heart sounds normal in character, but heard with unusual distinctness over the left apex.

Membranes and cartilages of the larynx normal. No impairment of sensation. Upon efforts at phonation, a long elliptical opening is seen between the bands and including the cartilaginous glottis. Both vocal bands are in the same position. Could find no history or evidence of any trouble along the track of superior laryngeal nerve.

DISCUSSION.

Dr. Cohen: There is a point in connection with the first case which is interesting, and that is the difficulty of whispering, or the inability to whisper. This condition, to which I have ventured to give the term apsithyria (lack of whisper), corresponds with the word aphonia, or lack of voice. This patient I saw some ten years ago. She was under the care of a neurologist, who consulted me on account of her inability to speak and to whisper. She communicated with others entirely by pencil and paper. But she used to whistle, and had adopted a peculiar habit of expressing Yes by one whistle and No by two whistles, and so on. This showed that the paralysis of the muscles of articulation was not complete. As it was evidently a case of functional aphonia, I suggested the use of the electric current to the muscles of articulation, with the result of curing her whisper. She was exceedingly emotional, and the gentleman under whose care she was put her to bed for some intercurrent complaint, and sent her abroad, and I never had anything professional to do with her after that time. I saw her eight or nine years afterward; she was well, married, and the mother of a fine child. She told me she had never lost her whisper. I have met with a few other cases in which there was inability to whisper as well as inability to speak. I do not think there is a real paralysis in these cases—paralysis either of the voice or of speech. I think we have that condition in which these patients can not "will" to speak or can not "will" to whisper—the condition described by Sir James Paget, of London, in connection with diseases of the urinary organs. If you can control these patients, and get them to will to do what they ought to do, you can cure them. Some cases you have of inability to swallow. The patients can swallow, but they can not or will not will to swallow, and you have to manage them by having a skilled nurse to stand over them, give them confidence, and force them to swallow. I am very glad to see the author has been able to include in his cases one of extreme abduction of the vocal band. This will add two more to the cases on record.

Dr. Glasgow: When Dr. Cohen commenced to speak I thought his case was due to a loss of will-power and not to an absence of muscular power. We often see these cases, and we can not always determine whether these persons can speak or not. It recalls an instance which occurred to me last year of a patient who was unable to speak, but was able to whisper; but this also was imperfect. Most of the conversation was carried on in writing. There was absolutely no change in the muscular powers of the larynx. Everything seemed to be perfect, so far as we could see by examination. I dismissed her by saying she could whisper if she wished to. A cure of this case was effected by prayer. It was on Thanksgiving Day. I first saw her in August. The minister prayed that the afflictions of the family should be taken away, that this daughter should be relieved from her infirmity, and at the end of the prayer she spoke. Now, there was a deficiency of will-power, I really believe, in this case. This case was the sequel of a prolonged typhoid fever. I should think that weakness of the muscles followed, and she found a sort of difficulty in speech, and, as it worked upon her mind, she thought she could not speak. I had assured her she could speak if she would; and after this I think she was waiting for nothing but an opportunity. This prayer produced the opportunity. After the prayer she spoke well. I do not think it was deficient will-power, but perverted will-power. I think we see many cases in young women. I think this explains a good many cases of aphonia without organic muscular change or action.

Dr. Hooper: I have always thought so-called hysterical aphonia purely functional. Although the patient is voiceless, the vocal bands are freely movable, as may be seen by asking the patient to laugh while being examined with the mirror. The statistics of the Throat Department at the Massachusetts General Hospital show that unilateral paralysis of the vocal bands occurs about once in two hundred and fifty cases. In the cases of paralysis which I have seen, I have never yet heard a patient with one vocal band immovable who was able to speak in a clear, natural voice, no matter what position the paralyzed band might be in. I can imagine, however, that in certain rare in-

stances, as in one case of Dr. Johnson's, the voice may be good. I agree with Dr. Johnson in the difficulty of determining the ætiological factor of many of these cases.

Dr. Rice: In a number of cases of hysterical aphonia seen lately I have been impressed with the frequency of the inaction of the transverse or arytænoidæus muscle. I think this muscle is more frequently affected than any other in hysteria. This is frequently seen, too, in acute inflammatory troubles of the larynx, it being the first muscle affected, and the sole cause of dysphonia and temporary disability of the voice. There is one case of hysterical aphonia I will mention, since the cure was so remarkable. It was the case of a young woman twenty years of age. She had no constitutional trouble that I remember, and her general health was apparently good. She had been unable to speak for five or six months, and I found the loss of voice was caused by a paralysis of the transverse muscle. She had been treated by a physician, who used electricity and strychnine. I was unable to benefit her. I received a letter from her three or four months after my treatment, in which she stated she had met with a runaway accident, had been thrown from a wagon, and since then had spoken perfectly. I saw her a short time after, and there was no paralysis. Another interesting case to me was that of a man who had a syphilitic history, and who was, in addition, phthisical. One of the vocal bands was ulcerated all along its free border; the other much swollen. Both arytænoids were in a state of ankylosis, the vocal bands being in the cadaveric position. The remarkable point about the case was this: when attempts at phonation were made, there was apparent a tremendous muscular exertion in the larynx, endeavoring to compensate for the non-movement of the vocal cords. The patient was able to produce a fair voice, husky in character. This was produced entirely by the approximation of the larynx above the level of the vocal bands—that is, by the action of the false cords.

A REPORT ON THE ORIGIN AND GEOGRAPHICAL DISTRIBUTION OF PHTHISIS PULMONALIS FOR THE STATE OF MICHIGAN.*

By E. L. SHURLY, M. D.,
DETROIT.

Mr. President and Gentlemen: The object of the investigation upon which this imperfect report is based is to ascertain, if possible, what, if any, influence is exerted by strictly telluric environment upon the causation of phthisis pulmonalis. The aërial and social factors of its ætiology have been for a long time freely and widely discussed, but the telluric aspect and geographical distribution, according to my observation, have received much less consideration, and perhaps deservedly, although it seems to me that we have too little knowledge on this point to warrant such a decision.

Circulars were sent out to the profession of the State of Michigan asking for data relating to the number of cases of phthisis pulmonalis which had *originated* only in the township or county where the practitioner resided, together with a statement of the number of such patients who were known to have hereditary predisposition, and whether primary or secondary. Although a large number of replies were received, I regret to say the number was somewhat less than I had hoped for.

As the number of physicians who keep notes of cases is small in the aggregate, I endeavored to shape the queries as concisely as possible, and to ask for so little that almost any practitioner could fill out the answer from memory and with the consumption of very little time. To those who were good enough to reply I feel greatly indebted, and I believe all who are interested in this subject will also share in this feeling.

I thought it advisable, even at the risk of wearying you, to precede the tables with a few extracts from the reports of Professor Winchell and Dr. Rominger, showing the topography of the State.

I am greatly indebted to Dr. A. W. Nicholson, lately of our State Board of Health, for the general and census tables, and to Dr. Erwin Wright for the preparation of the other data in the form presented.

Topography, Hydrography, and Geology.

"The two natural divisions of the State are distinguished by marked physical characteristics. They are completely cut off from one another by the Straits of Mackinac. The northern is rugged, with numerous rocky exposures; the southern consists of plains, plateaus, gentle undulations, and moderate hills, with very few outcrops of rocky strata. The northern peninsula is a mineral region; the southern, agricultural. The climates of the two peninsulas are as distinct as their location and topography."

"The climate of Michigan, both in summer and winter, is well adapted to the interests of agriculture and horticulture. Its marked peculiarity is attributable to the influence of the great lakes by which the State is nearly surrounded. It has long been known that considerable bodies of water exert a local influence in modifying climate, and especially in averting frosts; but it has never before been suspected that Lake Michigan, for instance, impressed on the climatic character of a broad region an influence comparable with that exerted by the great oceans."

"The influence of the sea in equalizing temperatures has long been understood. The immunity from unseasonable frosts secured by bodies of fresh water to localities in their immediate neighborhood has also been universally observed; but the fact that inland lakes of the size of Lake Michigan exert an ameliorating agency quite comparable with that of the Atlantic Ocean is something which has only been brought to light by recent thorough discussion of a wide range of meteorological data."

Distribution of Precipitation through the Seasons in Percentages of Total Precipitation.

	Spring.	Summer.	Autumn.	Winter.
Upper Peninsula	19·0	27·0	28·8	22
Lower Peninsula	25·8	28·7	27·3	19
Whole State	23·8	28·3	27·7	20

It appears that the northern localities experience a somewhat greater liability to dryness in all seasons. It must be

* Read before the American Climatological Association, May 28, 1885.

borne in mind, however, that the percentages given are percentages of the seasonable means.

"A general glance at the superficial configuration of the lower peninsula reveals a surface swelling gently from the shore toward the interior regions."

"Generally the lake shores are depressed."

"The rise of the peninsula from the level of the lakes is generally gradual, and in a few places only is it abrupt. The surface is of an undulating, hilly character; the hills are rounded, and never attain a very great height above the surrounding country. The southern peninsula is lower than the northern. The swell of the land forming the water-shed of this southern division coincides with a line drawn in a southwest direction from Port Austin, at the entrance of Saginaw Bay, to the southwest corner of Hillsdale County, where it enters the boundaries of the State of Ohio. Within the limits of Tuscola and Sanilac Counties the known surface elevation of this water-shed is about four hundred feet, while in Hillsdale, not far from the southern State line, some points with an elevation of six hundred feet are recorded; but the water-shed is probably not over five hundred feet high."

"This, which may be called the southeastern water-shed, is not broken through by any of the streams, though deeply excavated by the Huron River in Washtenaw County."

"The descent from the height of the water-shed to the lake shore is so gradual that a traveler in crossing the peninsula from either lake to the other, if he follows the river valleys, can scarcely perceive it. The northern division of the peninsula rises to nearly double the height of the southern part; its surface is more broken and diversified by steeper ascents from lake to terrace. Its highest points in the vicinity of Otsego Lake are, according to the records of the railroad surveys, eleven hundred feet from the lake level. Otsego Lake lies directly west of Thunder Bay, and not far from the northern terminus of an extensive high plateau with undulating surface, and an average elevation of from seven hundred to eight hundred feet."

"All the rivers of the northern part of the peninsula have their source within this plateau, which is dotted with a number of inland lakes, some of which, like Lakes Higgins, Houghton, and St. Helen's, are of large size. The terraces by which the descent from the plateau is made form a succession of broad belts; their sides are moderately steep and finely timbered; the lowest are wider, gradually slanting toward the shore, or overlooking it in bluffs of from forty to sixty feet."

In some places on the west side the bluffs are from one hundred to two hundred feet high, and Sleeping Bear Point, a promontory facing Lake Michigan west of Big Traverse Bay, is said to have an elevation of five hundred feet. Opposite this point, twelve miles out in the lake, the Manitou Islands rise abruptly to a height of two hundred feet above the water. South of the second correction-line the plateau rapidly declines toward Saginaw Bay. Between the north and south parts of the peninsula a depressed strip of land extends from Saginaw Bay to the mouth of the Grand River on Lake Michigan, having rarely more than one hundred feet elevation.

An astonishing number of smaller and larger inland lakes are found in every part of the peninsula; all have crystal-clear water, and the principal supply of the head branches of our rivers comes from them. The more important rivers collecting the waters of the western slope of the peninsula are the St. Joseph's, Kalamazoo, Grand, Muskegon, and Manistee. The three first named have their sources in close proximity to the elevated lands of Hillsdale and Jackson Counties.

From the same swell of land the River Raisin emanates, flowing outward into Lake Erie. The Raisin River enters the lake near Monroe; it drains the southern part of Washtenaw County, and draws its branches from a number of small lakes in the southeast corner of Jackson County through its main north branch. The south branches have the drainage of Lenawee County.

The St. Joseph's, Kalamazoo, and Grand Rivers almost touch each other within the small area of a few square miles in the County of Hillsdale. The St. Joseph's River originates in a number of small lakes and marshes in Hillsdale County, and enters Lake Michigan at the village of St. Joseph.

The streams which form the head-waters of the Kalamazoo River rise in Hillsdale County. The river runs north, west, and northwest, and falls into Lake Michigan near Saugatuck.

Grand River springs from a few lakes in Jackson County; it runs north and opens into Lake Michigan near Grand Haven.

Huron River collects its waters from innumerable lakes and marshes in Livingston and Oakland Counties, flows southwest, and at Dexter turns southeast and retains this direction until it enters the Detroit River in the northeastern corner of Monroe County.

Clinton River drains the eastern part of Oakland County and all of Macomb County, entering Lake St. Clair near Mount Clemens.

Black River is remarkable for its southern course for nearly fifty miles parallel with Lake Huron, at a distance of only five or six miles from it. It begins in the northern part of Sanilac County, and enters St. Clair River near Port Huron.

Saginaw River is the receptacle of a whole system of rivers. By the Tittibawassee River the waters of the north and west are led into it. The Shiawassee collects from the south, the Flint River from the south and southeast, and finally the Cass River brings its waters from the northeast and east.

The river system of the northern part of the peninsula consists of the following rivers: Commencing at the southeast side, we first find the Rifle and Aux Grès Rivers, which drain the southeastern shore-belt surrounding the before-mentioned high plateau. Au Sable River is the next largest river north of them. It draws its branches right from the high plateau, and drains Otsego in the north end of it.

Thunder Bay River, opening into Thunder Bay, spreads its arms north, west, and south, reaching the foot of the high plateau. The Cheboygan River on the north of the

peninsula forms the outlet of three large lakes—Black, Mullet, and Burt. These lakes are fed by rivers of good size. On the west side of the peninsula two large rivers deserve to be mentioned.

Manistee River originates very near the head-waters of the Au Sable River on the east side. Its mouth is at Manistee.

Muskegon River is larger than Manistee; its branches extend to the top of the central high plateau, and are fed by Higgins and Houghton Lakes. Of all the rivers mentioned, none are navigable. The water-power afforded by these rivers is ample, and those the branches of which flow through timbered lands are of vital importance to the lumber business as mediums for the transportation of felled timber from otherwise almost inaccessible parts of the interior to ports or railroad stations.

The rivers have all eroded their valleys into the loose drift masses which almost universally cover the surface of the peninsula in great thickness. Only in rare instances have they been deep enough to touch the solid rock ledges below the drift, or, if such deep cuts did exist, they have filled them up with *débris*, and the beds of the present streams lie high above those of former times. The peninsula was, in its original condition, heavily timbered, with the exception of a few marshy flats. Climate and quality of the soil determine the character of the vegetation. In the southern part of the peninsula deciduous trees, particularly hard-wood timber, prevail. Pine is only sporadically intermingled. The mildness of the climate favors the growth of the oak, hickory, walnut, poplar, etc., which abound here, but become rarer farther north, where beech, maple, and birch take their place. The sandy soil of the central high plateau is most congenial for the growth of pine forests, which have taken possession of nearly the entire district. The marshy condition of some other places adapts them for the tamarack, elm, asp, and willow trees, or for the growth of the cedar, while a few parts of the high plateau, proving too sterile even for the pine, afford sustenance to nothing more than a stunted scrubby growth of *Pinus banksiana*, and a few creeping herbs which attempt to hide the barrenness of the scene. Such barrenness has, in some instances, been caused by fires which annihilated forests of large area, totally denuding the surface, and leaving it exposed to the burning rays of the sun and to the exsiccating winds, and unable for a long time, if not for ever, to recover its former well-timbered condition.

"The entire surface of the peninsula is covered by heavy drift deposits, with the exception of a few limited localities in which the drift, subsequent to its deposit, has been washed off by the floods, or by rivers curving their course deep enough to touch the rock-beds of older formation. These drift masses are almost the same as those of the upper peninsula. The material has been changed somewhat, by the admixture of rock-*débris*, from the formations encountered by the moving glaciers in their southern course. The glacier-drift spreads itself in a compact body over the entire surface of the lower peninsula, in evidence of which fact the rock-beds, wherever they are found denuded and the nature of the rock has been capable of preserving the marks, bear the traces of its motion on their scratched surface. Not all the drift material found on the lower peninsula has been transported there by glaciers; a large portion of it must have been carried southward by water, partly in suspension—as mud and sand—partly frozen with floating ice—as the coarser material, the gravel and the bowlder.

"The glaciers deposited moraines—heaps of rubbish composed of all kinds of rock-*débris* in every degree of comminution, from the large bowlder down to the impalpably fine clay.

"Much of the drift is not found in this orderless form of moraines, but is disposed in well-stratified layers, assorted, according to the weight of its particles, by water-currents."

A long time of submergence of the land must have followed the glaciers. The surface of the highest points of the peninsula, 1,100 feet above the level of the lakes, is formed by stratified drift-sand, mixed with pebbles.

"The older glacier-drift and the later deposit of floods and icebergs are materially of the same composition; both are made up of clay, sand, gravel, and bowlders of detritus from crystalline and metamorphic rocks, mixed with *débris* of younger sedimentary strata."

The coarse bowlder-drift all through the southern part of the peninsula appears not to occupy the lowest position, in which most frequently a hard, dark blue, sandy clay, with pebbles and some bowlders intermingled, is found in layers of considerable thickness. It is known among laborers by the popular name of hard-pan.

"Bog-iron occurs very frequently in small patches of marsh lands in all parts of the State."

"As another surface deposit, peat has been mentioned. Innumerable larger and smaller patches cover the swampy surface depressions throughout the whole State."

The soil of the lower peninsula, being a drift-soil, is generally very deep, and contains all the chemical constituents of a good soil.

The assortment of the drift-soil into clay, sand, and gravel determines its character as the layers happen to occupy the surface positions, while by intermixture a great variety of intermediate shadings in the quality of the soils is locally produced under atmospheric influences. The distribution of soils over the State is sometimes very unequal and changeable, so that within limited areas, and often within single farms, a number of variations in the character of the soil are represented. But with the differences seen in the surface configuration of certain districts is also usually found a corresponding contrast in the quality of their soil. The high plateau in the northern part of the peninsula has its peculiar soil, a thick, uniform mass of fine sand, containing few pebbles and a small proportion of argillaceous constituents. In accordance with it is its vegetation; the pine-tree finds a congenial home in these sandy hill-lands, and their surface is overgrown with splendid forests of this tree, to the exclusion of almost every other kind.

"Other districts—represented by lowlands adjoining the lakes, and, to all appearances, within comparatively recent times parts of the lakes' bottoms—are covered by a stiff clay soil overgrown with elm, ash, and kindred trees, as, for instance, the lower part of Saginaw Valley and a strip of land bordering Detroit River, from Monroe up to Lake St. Clair.

"The climate of the peninsula, which is the other principal factor in its productiveness, is over the whole extent temperate, extremes of heat or cold being prevented by the surrounding lakes. From the northern to the southern end all the cereals can be planted with little risk of failure. The northern part is somewhat cold, its vegetation coming out two weeks later than in the south, and the winter setting in that much earlier, which affects somewhat the raising of the more tender fruit crops, as grapes, peaches, etc.

"The grape and the peach do well in the southern part of the State, and particularly near the shores of the great lakes, where the foggy, humid air prevents late frosts, the greatest enemy of these fruits. The west shore up as far as Muskegon has become famous for its peaches and other small fruits."

"Beneath the drift the peninsula is underlaid by regularly stratified rock-beds, in undisturbed horizontal position, which represent the upper part of the palæozoic strata."

In the following report it will be seen that under the heading of County is given the name of each county; under the heading of Population is given the population by counties in 1870 and 1880, and under the heading of Number of Deaths by Phthisis is given the total number of deaths from phthisis from 1869 to 1882, inclusive. The column marked Number of Cases originating in County gives the cases reported to me from various physicians as having originated in their county, with the year of their appearance. Of these, the remaining columns, marked Primary and Secondary, will show the number of cases as far as known which were primary, and those which arose secondarily to some other malady:

It will be seen by these tables that the whole number of deaths from phthisis pulmonalis, as reported to the State Board of Health, from 1869 to 1882 (thirteen years) is 22,103, or an average of 1,700 a year. Of these, 1,241 were reported in 1869 and 1,979 in 1882.

During 1882 rain fell 179 out of the 365 days, with a total fall of 30·31 inches, which was about the average fall for the preceding ten years. The mean temperature for 1882 was 51·2, which was slightly higher than the average for the preceding ten years.

The whole number of cases reported to me as having originated in the State between the years 1857 and 1885 is 1,370, and of these, 673, or nearly one half, were reported as primary, while 205 were reported as having been secondary to some other disease.

Of the total number of original cases (1,370) from 1857 to 1885, 602, or a little less than one half, occurred between the years 1879 and 1885, or during a period of six years.

The total population of the State, according to the census, in 1870 was 1,184,059, and in 1880 was 1,856,100, showing an increase of 672,041; so that proximately, so far as learned, the percentage of deaths from original cases to population would be about $\frac{7}{100}$ per cent., which no doubt is somewhat below the truth; but, as before remarked, these statistics are necessarily inaccurate (as are all United States vital statistics). However, if enough has been elicited to awaken an interest in the further investigation in this line, the work may not prove entirely valueless.

Note.—A very full and able account of the climate and topography of Michigan, illustrated by numerous maps, by Dr. H. F. Lyster, of Detroit, may be found in the "Report of the Michigan State Board of Health," for 1878.

HOW TO TREAT HÆMORRHOIDS BY INJECTIONS OF CARBOLIC ACID.

By CHARLES B. KELSEY, M. D.

The many requests which I have received from members of the profession for an exact description of this method of treatment have decided me to write the following communication, even at the risk of repeating what I supposed I had already made sufficiently clear.

The injection of hæmorrhoids with carbolic acid, though apparently a simple and trivial affair, is to be regarded in the light of a surgical operation, and should not be undertaken by the practitioner until he has surrounded himself and the patients with all the safeguards at his command.

There are two accidents which may happen in these cases, and for which the operator must be on his guard. One is undue ulceration, the other is abscess. Ulceration is the result of using a strong solution, which causes a distinct slough of the tumor injected. The resulting ulcer is seldom larger than a silver quarter, and I have never known it to give rise to serious trouble or to refuse to heal kindly with proper local treatment. When it occurs it is well to cease further injections and to deal exclusively with this condition until it is healed. Applications of nitrate of silver, iodoform, calomel in powder, etc., are usually sufficient to induce cicatrization. The ulcer is not generally painful, the discharge is about the only symptom of which the patient complains, and the complication is not therefore to be considered as a serious one.

It will at once be asked what strength of solution is capable of producing a slough? I can not say. The worst one I ever produced came from an injection of a fifteen-per-cent. solution, and I have deliberately tried to produce one in a large hæmorrhoid by the use of undiluted carbolic acid, and failed to get anything more than a hard tumor of the size of the end of the thumb around the injection. The individuality of the patient seems to exert a decided influence, and, given a certain standard strength of solution—say thirty-three per cent.—it is impossible to predict beforehand in how many patients it will produce a slough and in how many it will produce a simple induration. Of course, as a general rule, it can be stated that weak solutions are less apt to produce sloughs than the stronger ones, but beyond this my experience does not yet enable me to go, and I do not consider the question as one of very great importance; for these ulcers which result from a slough heal fully as well as the wounds which follow either the ligature or the clamp, and it is with these two methods of operating that I wish the treatment by carbolic acid to be compared. I hold it to be a surgical procedure, comparable in its results with either of these, and to be judged on its merits as compared with them. I believe that it possesses many advantages over either of them.

The second complication is abscess, and these are of two kinds—one trivial, the other serious. In two or three cases I have seen the following chain of events: An injection of medium strength being made, the patient has returned after a few days complaining of a painful swelling. An examination has revealed a tumor of the size of the end of the thumb situated just at the margin of the anus, covered with skin on the outside and mucous membrane on the inside and containing pus. If left to itself, such an abscess will often discharge on both the mucous and cutaneous aspects, the two openings being free and close to each other, and the cavity will close spontaneously. An incision on the cutaneous surface, though it will relieve pain and evacuate pus, may yet not prevent a spontaneous opening on the mucous surface. When the two openings have formed, the result is a subcutaneous fistula at the verge of the anus, but one which in its results is a very trivial affair, and which, if it does not heal spontaneously, can easily be laid open in the surgeon's office, and dressed with lint from the bottom.

The other abscess is a much more serious matter, and I have no doubt that it can be produced, and in some cases has been, by an improper use of the acid. I refer to a deep abscess of the cellular tissue in the ischio-rectal fossa. Such cases have been described and are quoted as the chief objection to this method of treatment. They are due to the injection of too strong a solution, or of the undiluted acid, either into a small tumor or into the cellular tissue entirely beneath the tumor. The pure acid may be inserted *into* a large hæmorrhoid and cause a limited slough which will result in a perfect cure. The same injection given *below* a small tumor is pretty likely to cause a considerable cellulitis. It is in this way that I explain this unfortunate accident, which is rare at the most, is a result of the im-

proper employment of the means at the operator's command, and ought not to be considered a valid objection to the plan of treatment.

I have said that the injection of hæmorrhoids reached the dignity of a surgical operation, and should be judged in comparison with other operations for accomplishing the same end. This will almost certainly be found to be the case in any extended experience. The suffering is not always trifling; the nervous strain of submitting to any plan of treatment is not inconsiderable; the affection itself is sometimes a serious one, and, as I have already said, the operator should surround himself with all the safeguards within his reach. During the past summer I was called upon to treat an old gentleman, the mayor of a small town in Ohio, living in a high, cool, country region, but much depressed with business losses and worry. He came to New York in the middle of the hot season and submitted to treatment. The hæmorrhoids were the worst which up to that time I had ever treated by this method. The sphincter was much relaxed; the tumors had been down for twenty-five years without being replaced, and were very large and vascular. There were three distinct masses, each of about the size of a hen's egg. The case was not an attractive one, considering the age and condition of the patient and the hot weather, but I undertook it. Into the largest of the three tumors I injected five drops of a fifty-per-cent. solution. It was followed by a good deal of pain and loss of sleep for two nights, with some constitutional disturbance. On the third day, the pain of the first injection having somewhat subsided, I injected five drops of pure acid into the second tumor, and had much less trouble than with the fifty-per-cent. solution in the former case. After three days more I again injected the same amount of pure acid into the third tumor. Both of these last applications caused a distinct slough with resulting ulcerated surface and free discharge of bloody matter. After a few days more I returned to the first tumor, which had not sloughed but simply become indurated, and injected five drops of pure acid into that. The applications were all made within the space of two weeks. During this period the patient allowed his bowels to become constipated, and I had to clean them out with repeated copious enemata. There was at one time some vesical irritation and decrease in the amount of urine, whether from direct absorption of carbolic acid or from reflex irritation I do not know, and at the end of the treatment the patient was considerably reduced in strength—so much so that I put him upon the most nourishing regimen with bark and whisky. Just as he seemed on the point of rallying I discovered a small abscess in the perinæum, which was opened, and healed kindly, having no connection with the rectum. After recovering from this and gaining a considerable degree of health he went to his home in Ohio, and was immediately brought to bed with a second, larger abscess on the buttock. From this he also made a good recovery, and has ever since been perfectly well, the hæmorrhoids causing no disturbance whatever.

This was a bad case, and for that reason I am willing to consider it as a test one. The hæmorrhoids were the largest I have ever seen operated upon by this or any other operation. The patient was seventy years old, and, though free from organic disease, was not in good general condition. The piles were cured by four injections of carbolic acid. It is true he suffered pain, he had some vesical irritation, and he had two abscesses due to his general enfeebled condition, but having no connection with the rectum. Taking the case as it stands, the operation will compare very favorably with either Allingham's or Smith's. The man was not confined to his bed at any time, and, moreover, would not submit to either of the other operations under any circumstances. Being one of the *worst* cases I have ever had with carbolic acid, I am still willing to place it in comparison with the *average* case of operation by the ligature, looking at both in the light of surgical procedures of considerable magnitude and importance.

The objections to and possible complications of this method of treatment are, therefore, easily enumerated. They are, 1, pain; 2, vesical irritation where strong solutions are used; 3, marginal abscess; 4, deep cellulitis. *In the majority of cases the patient will escape them all.* Deep cellulitis I should suppose to be about as frequent after this operation as pyæmia after the ligature. Marginal abscesses may occur at any time, but are easily treated. The vesical symptoms never follow any but the more powerful injections, and the pain is very variable and can not be predicted from the strength of the solution used. I have injected five minims of pure acid into a large tumor without the patient either knowing when it was done or appreciating the slightest sensation afterward. I have injected a fifteen-per-cent. solution into a small tumor and caused considerable suffering. Speaking in a general way, I do not expect much pain from a weak solution, but, nevertheless, it is sometimes met with, and I have ceased to predict its presence or absence. If it comes with any solution I am not surprised, and if it does not come I am pleased. It is, however, an exception to meet with it to any marked degree.

As far as I have been able to reduce this treatment to a matter of rule the results are as follows:

1. Use only the purest crystallized carbolic acid, the purest glycerin, and distilled water in the preparation of the solutions. Each, when prepared, should be perfectly colorless and clear, the acid being in perfect solution. The glycerin is added to the solution of carbolic acid in water in just sufficient quantity to make a clear fluid, and the amount is not important. As soon as a solution begins to assume a yellowish tint it should be replaced by a fresh one.

2. Use only the finest and most perfect hypodermic needles and a perfectly working, clean syringe with side-handles. After each injection when the syringe is put away, clean it thoroughly, to be ready for the next time.

3. The treatment may be applied to every variety of internal hæmorrhoids, no matter what their size. It is not applicable to external hæmorrhoids, either of the cutaneous or the vascular variety, both of which may be treated by better means.

4. Before making an application give an enema of hot water, and let the patient strain the tumors as much into

view as possible. Then select the largest and deposit five drops of the solution as near the center of the tumor as possible, taking care not to go too deep so as to perforate the wall of the rectum and inject the surrounding cellular tissue. The needle should be entered at the most prominent point of the tumor. If the hæmorrhoid does not protrude from the anus, a tenaculum may be used to draw it into view. After the injection has been made the parts should be replaced, and the patient kept under observation for a few minutes to see that there is no unusual pain. The injection will cause some immediate smarting if it is made near the verge of the anus; if made above the external sphincter, the patient may not feel the puncture or the injection for several minutes, when a sense of pressure and smarting will be appreciated. In some cases no pain will be felt for half an hour, but then there will be considerable soreness, subsiding after a few hours. If it increases, instead of disappearing, and on the following day there is considerable suffering, which may not perhaps be sufficient to keep the patient on his back, but is still enough to make him decidedly uncomfortable, it is a pretty good indication that a slough is about to form. For the reason that it is impossible to tell absolutely what the effect of an injection is to be until at least twenty-four hours have passed, it is better to make but one at a visit and to wait till the full effect of each one is seen before making another. If on the second day there is no pain or soreness, another tumor may be attacked, and this will often be the case.

5. The strength of the solution must be regulated by the nature of the case, and in my own practice varies from five per cent. to pure crystallized acid. In a large, vascular, prolapsing tumor, which is well defined and somewhat pedunculated, five drops of pure acid may be used with the expectation of producing a circumscribed slough which will result in a radical cure. A thirty-three-per-cent. solution under the same conditions will probably produce consolidation and shrinkage without a slough, but the injections will have to be repeated several times. A small tumor which protrudes but slightly, is not pedunculated, and can be seen and felt as a mere prominence on the mucous membrane, may be cured by a single injection of a five-per-cent. solution, which will cause it to become hard and decidedly reduce its size, while an injection of a fifty-per-cent. solution might make considerable trouble, the remedy being too powerful for the disease. Guided by this principle, some experience will soon determine the choice of the solution. There is no arbitrary rule which can be applied to every case. As in any other surgical operation, some cases will be more satisfactory than others, and an occasional accident must be expected; but, on the whole, it seems to be the best method of treatment yet devised.

25 Madison Avenue.

The New York Academy of Medicine.—The Section in Practice of Medicine will hold a meeting on Tuesday evening of next week, in the Academy's parlors. Dr. R. C. M. Page will read a paper on "Bright's Disease," and the discussion of the subject will be participated in by Dr. E. G. Janeway and Dr. Francis Delafield. A discussion on the question "Is Croupous Pneumonia an Inflammation or a Fever?" will be opened by Dr. William H. Draper.

Clinical Reports.

ROOSEVELT HOSPITAL.

Clinical Remarks by Dr. Henry B. Sands.

Abscess of the Knee.—Osteitis of the Tibia.—Excision of the Knee Joint.

We have before us, gentlemen, two cases of strumous disease of the knee:

Case I.—The first patient is a man, twenty-three years old, who has had disease of the left knee joint for four years. I will postpone giving you a complete history of his case until some future occasion, when he will probably undergo the operation of excision of the joint. To-day I intend simply to evacuate a large abscess which has formed since the patient entered the hospital five weeks ago. At that time the character of the disease was evident. The knee joint was semiflexed, painful, and swollen, its circumference being two inches and a half greater than that of the sound one. The swelling was fusiform, and did not fluctuate. The patella was in contact with the femur, and was not adherent. Pain was felt on pressing together the articular surfaces, and also on making flexion or rotation, which was accompanied with the crepitus characteristic of erosion of the articular cartilages. Further evidence of disorganization was found in the existence of a fistulous opening on the outer side of the knee, and in a partial luxation backward of the tibia.

I considered the case a proper one for excision; but, in consequence of the recent development of an abscess of considerable size on the inner aspect of the joint, I have decided to defer this operation until the abscess has been opened and its walls have been allowed to contract. It is doubtful whether the abscess communicates with the cavity of the joint, because the latter is not at all distended, and because firm pressure upon the abscess fails to displace its fluid contents. In any case, however, incision is the proper remedy.

Having now opened the abscess, and permitted the discharge of several ounces of well-formed pus, I am unable to discover any communication with the joint cavity. A probe introduced through the sinus on the outer side of the knee also fails to enter the joint. I will conclude the operation by irrigating the abscess with a solution of mercuric bichloride, 1 to 1,000, inserting a drainage-tube dusted with iodoform, and applying a wood-wool dressing.

Case II.—C. R., twenty-four years of age, was sent into the wards from the Out-door Department, March 2d. Family history good. The patient is a healthy-looking woman, who denies syphilis. She states that eleven years ago there occurred spontaneously a painful swelling of the right tibia near its middle and upon its inner surface. This swelling has never disappeared, and has usually been painful. She has taken iodide of potassium at various times, and is now recovering from the effects of mercurial treatment, which has failed to afford relief.

On examination, there is found a painful, hard swelling over the right tibia at the junction of its lower and middle thirds on its inner surface. The swelling is apparently connected with the bone and periosteum. It is quite firm, and shows no point of fluctuation.

The prominent features of the case are the long duration of the disease and the mildness of the symptoms, which are those of chronic osteitis or periostitis. Occasionally, as has happened in the present instance, internal remedies prove to be useless, and in these circumstances relief may often be afforded by freely incising the periosteum. I shall resort to this expedient now,

and shall, perhaps, also trephine the thickened bone, so that I may be able to explore the medullary canal and liberate any inflammatory products that may be found there.

Having divided the soft parts down to the bone, and removed a disc of the latter by means of a trephine, I can discover nothing besides an inflammatory thickening and condensation of the affected parts, no signs existing of caries, necrosis, or abscess. An iodoform dressing will be applied, and the wound allowed to heal by granulation. Some benefit to the patient may be anticipated from the operation.*

Case III.—This is one that requires excision of the knee. The patient is a German, twenty-nine years old, whose mother died of pulmonary consumption, and who, fourteen years ago, had symptoms of phthisis, which, however, were of short duration. In 1875 the distal phalanx of his right index-finger was amputated for what seems to have been a tuberculous affection of the neighboring joint, accompanied with cheesy abscesses near the elbow and in the axilla, which remained open for eight months. About the same time a cold abscess formed below his right knee. This was incised, and healed three months afterward. Two years ago the knee joint began to swell and became somewhat painful. Gradually the disease grew worse, and the patient found it difficult to walk, chiefly on account of flexion of the knee, for which, he says, he was treated last winter by tenotomy of the hamstrings. When he entered the hospital, December 10, 1883, his right knee was swollen, partly in consequence of a moderate effusion of fluid in the joint cavity, and also on account of a thickening of the capsule and other deep soft tissues. The circumference of the knee over the patella was sixteen inches, that of the sound knee being fourteen. The patella was movable. Flexion could be made to nearly a right angle, and extension to nearly a right line, without causing pain or crepitus. Deep fluctuation could be felt across the joint above the patella. In addition to the joint-disease, a large cold abscess occupied the upper third of the leg on its inner and posterior aspects, fluctuation being distinguishable as high as the flexure of the knee. This was freely opened, on December 15th, by my house surgeon, who made two incisions at opposite points, evacuated the abscess as thoroughly as possible, washed it out with a solution of mercuric bichloride, inserted rubber drains, and applied a peat dressing. On January 15, 1884, three weeks ago, I opened and drained the knee joint, making an incision about one inch in length on each side above the patella. During this operation I discovered that the articular cartilages were extensively destroyed, leaving the bone exposed, and I should have performed excision at once had I obtained the man's consent. At present, however, his condition is very favorable for the operation, and it is doubtful whether anything has been lost by the delay. The knee may be said to be neither better nor worse; it is slightly reduced in size, yet we shall find abundant evidence of disorganization when the joint is exposed to view. But, meanwhile, the large cold abscess referred to has undergone a remarkable change, having shrunk to the dimensions of a narrow sinus, which will not interfere with the success of excision.

Regarding the propriety of undertaking an operation I think there can be no doubt. The diagnosis of tubercular or strumous arthritis is made sufficiently evident by the clinical history, and has been corroborated by the discovery of tubercle bacilli in the fluid obtained from the joint, which was examined microscopically by Dr. Hall. The duration of the disease and the existence of suppuration render recovery, even by ankylosis, extremely improbable, and the only point to be decided is whether to perform excision or amputation. The patient's own preference for the former operation, the fact that he is an adult, his good general health, the absence of extensive sinuses communicating with the joint, the slow progress of the disease, the probability that the bony tissue has not been extensively destroyed, the increased chances of success afforded nowadays by antiseptic methods of operation—these are mainly the circumstances which induce me to make an attempt to save the limb by resorting to excision.

Having now completed the operation, I will briefly remind you of its principal points of interest. A broad antero-lateral flap, the lower margin of which corresponded with the level of the tubercle of the tibia, was reflected upward, and the joint exposed by cutting through the ligamentum patellæ. Many other forms of incision have been adopted, but this one I prefer as being convenient and as affording ample space for the removal of the diseased parts. After dividing the lateral, capsular, and crucial ligaments, the interior of the joint was thoroughly exposed to view, and it was then discovered that, as we had anticipated, the degenerative changes were most striking in the soft parts, the synovial membrane being everywhere greatly thickened and covered with exuberant, pulpy granulation tissue. Partly by the use of a sharp spoon, but chiefly with the aid of scissors, the diseased synovial membrane was completely removed. This step of the operation is tedious, but important, as there is reason to believe that failure often results from neglecting to perform it thoroughly. The synovial pouch, or *cul-de-sac*, which lies behind the quadriceps extensor, is somewhat difficult of access, as well as the synovial membrane at the back part of the joint, which can be efficiently dealt with only after removal of the articular extremities of the femur and tibia. The cartilages were extensively diseased, and at some points had disappeared, leaving the bone bare and soft. A thin slice of bone was sawed from the tibia and an inch removed from the femur. The patella was extirpated, and a small carious cavity in the head of the tibia scraped out with a gouge. The sinus in the leg was also explored and well scraped with a sharp spoon. It did not seem to communicate with the joint. To secure accurate contact of the sawed bony surfaces, three steel nails were driven into the femur and tibia, two from above downward through the condyles into the head of the tibia, and one from below upward in the median line. These nails perforated the skin, beyond which they were allowed to project about an inch. Bone-drains were inserted into the wound at four different points, and a rubber drain was introduced into the sinus of the leg. The wound was closed with a continuous catgut suture, and covered with bichloride gauze and a bag of wood-wool. Finally, the limb was firmly secured in a long posterior metal splint provided with a foot-piece. Such a splint gives adequate support to the limb, and is preferable, in my judgment, to the more complicated kinds of apparatus which have been invented for the same purpose. One object of the operation being to cause a fusion of the sawed bony surfaces, motion of the limb will be carefully avoided, and the dressings changed as seldom as possible.

* Pain diminished immediately after the operation, and disappeared entirely on the fifth day. It had not returned when the patient left the hospital, on the seventeenth day, the wound at that time being nearly healed.

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

The Medical Student's Essentials of Physics. By Condict W. Cutler, M. D., late House Physician, Bellevue Hospital, etc. New York: J. H. Vail & Co., 1884. Pp. 192.

THE
NEW YORK MEDICAL JOURNAL,

Edited by FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 14, 1885.

THE BOARD OF HEALTH'S ESTIMATE.

MR. JAMES GALLATIN has written a letter to the Board of Estimate and Apportionment, in which he protests against certain items in the Health Department's estimate of the funds it will require for the year 1886. In the first place, as to the allowance of $12,200 for the attorney's and counsel's office, he thinks that a young attorney, at $1,200 a year, would be fully competent to write "lawyer's letters" for the board, and that any other further legal assistance required in carrying out the present policy of the board could be readily obtained by an occasional detail from the Corporation Counsel's office. As to the allowance of $24,000 for twenty additional sanitary inspectors, Mr. Gallatin says that, if these additional inspectors are needed, it is only because the time and the energies of the present inspectors are wasted in repeated inspections of nuisances, the board having failed to secure the prompt abatement of these nuisances by inflicting the penalties prescribed by the law. The expenditure of the $2,000 allowed for marshal's fees is, he thinks, in great part a scandalous waste of the city's funds; and, to substantiate this criticism, he remarks that, instead of compelling unsuccessful defendants in civil suits to pay the fees, the board very obligingly pays the fees for them. Finally, he protests in general terms against any increase of the appropriation for the department, on the grounds of wastefulness in its expenditures and inefficiency in its management; and he expresses the opinion that a considerable reduction of the appropriation would not be accompanied with any injury to the public interests.

This is a scathing arraignment of the Board of Health, but it must be confessed that, in the pamphlet issued by Mr. Gallatin, he accompanies his letter with sundry citations, including that of the recent action taken by the Grand Jury, that go far to show that a strict and prompt enforcement of the penalties which the board is empowered by law to impose would result in a great saving of funds, and do away with the assumed need of additional sanitary inspectors. On the other hand, it should not be forgotten that much is left to the board's discretion in this matter, and that, inasmuch as sanitary requirements are almost always fraught with hardship, and are very generally regarded as odious, the board's leniency should not be too harshly criticised so long as it can be shown to be impartial. The truth seems to be that penalties should be prescribed for infractions of a sanitary code to be made by the Legislature itself, and not by the Board of Health, and that the enforcement of these penalties should then be made mandatory upon the board—the code, of course, to include only the minimum of requirements. We should then be in favor of the most ample appropriation, the remuneration of the present inspectors to be increased, however, rather than their number to be added to. As regards the legal expenses estimated by the board, they do seem unnecessarily large.

LIFE INSURANCE AND THE FAMILY PHYSICIAN.

THE question of the value of the family physician's certificate as to the condition and health-history of any given individual whose life is proposed to be insured is one that has often been discussed more or less fully, and one that is doubtless correctly appreciated in the main by the life insurance companies. It has lately been made the subject of public consideration in some of the German journals, particularly the "Deutsche Medizinal-Zeitung" and the "Allgemeine Versicherungs-Presse." From what we have seen in those journals, we fail to perceive that any particularly new light has been shed upon the matter, but it is one that will bear consideration from time to time.

From the family physician's standpoint, it is no doubt a nuisance to be required to furnish a sworn statement in which for a trifling fee, if indeed for any at all, he is expected by the "risk" (who in many cases has never really been his patient) to furnish a clean bill of health, without any ifs or ands, and by the company to communicate without reserve anything that he may know, or infer, or surmise, bearing in the contrary direction. On the other hand, the company's medical officer naturally gets to have an overweening confidence in his own powers of physical exploration, and in his capabilities for making a retrospective diagnosis; and is, hence, apt to chafe under the implied obligation to take a *tertium quid* into consideration. In view of these two embarrassing circumstances, it may well be doubted if the family physician's certificate often throws much light on the real state of the case. Nevertheless, life insurance is in some sense the right of anybody who can pay for it, and who can not be shown beyond reasonable doubt to be a proper subject for it. It is undeniable that in certain cases the family physician can conscientiously add information which will put a new color to the facts and statements elicited in the company's examination—sometimes to the applicant's just advantage, and sometimes in furtherance of the company's safety. Hence, the family physician's certificate can scarcely be denied to be occasionally an important factor in leading to an equitable decision.

APOTHECARIES' WEIGHT AND MEASURE.

ON more than one occasion we have pointed out the shortcomings of the metric system as applied to prescription-writing. Its peculiarities satisfy little else than a sentiment, while one of them—the decimal point—is so much of a stumbling-block in actual practice that probably in not a few instances mistakes involving loss of life have been due to it. Only last week we alluded to a dispenser's error that was attributed by him in part to the confusion into which he was thrown by a prescription written according to the metric system. We have nothing to say against the use of the system in strictly laboratory work, even of a pharmaceutical nature, but we can not conjure up a

valid argument against dropping it once for all in the matter of prescriptions. It is, therefore, with the greatest satisfaction that we have read an article in the current number of the "Pharmacist," contributed by Mr. Oscar Oldberg, whose name deservedly carries with it great weight in regard to such questions. As Mr. Oldberg states, he has for several years been an earnest advocate of the adoption of the metric system in this country for medical and pharmaceutical purposes, and it is very much to his credit that he now frankly abandons his former position, especially as he gives the most cogent reasons for so doing.

While he rejects the metric system, Mr. Oldberg thinks it desirable to connect our system with it, and he shows how this could be done by modifications of our apothecaries' weight and measure that would be so trifling as scarcely to affect their present value in prescription-writing. There is no reason, he says, why we should not modify a system that has come down to us from colonial times, especially as it is no longer adhered to in Great Britain. The minim has shown itself to be a most useful unit of measure, its great practical advantage being its approximation to the drop of most liquids at ordinary temperatures. For convenience in dividing the fluidrachm, he proposes that it should consist of sixty-four minims instead of sixty, in which case we should be able to write one half, one quarter, one eighth, one sixteenth, and one thirty-second of a fluidrachm, each of which quantities would represent a certain number of whole minims. The new fluidounce, which would contain eight of these fluidrachms, might be made equal to thirty-two cubic centimetres, and therein would be found a convenient point of connection between the proposed system and the metric system. As the present fluidounce is equal to 29·573 cubic centimetres, it will be seen that the change required would be practically unimportant as concerns doses, the strength of solutions, and the like. For the details proposed by Mr. Oldberg we would refer our readers to his article in the "Pharmacist," a careful reading of which we would commend to them.

MINOR PARAGRAPHS.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

The volume of "Transactions" for the current year has reached us, and we find that it includes many papers and discussions of more than transitory interest. The volume bears a Syracuse imprint, and the typography seems to us an improvement on that of most of the volumes of the series. The appendix, although brief, is particularly valuable, since it gives, either in full or in abstract, such of the Acts of the Legislature of 1885 as are of interest to the medical profession. The lists of the members of the society, and of the medical societies of the counties, are published in a separate volume. The secretary, Dr. William Manlius Smith, of Syracuse, is to be congratulated upon the creditable appearance of the volume.

It appears that the delegations from eighteen constituencies will become vacant February 1, 1886, and should be filled in time for the delegates to attend the next annual meeting. These constituencies are the medical societies of the counties of Chenango, Clinton, Columbia, Cortlandt, Erie, Hamilton, Herkimer, Kings, Madison, St. Lawrence, Suffolk, Ulster, Washington, Wayne, and Westchester, the medical department of the University of the City of New York, the New York Academy of Medicine, and Bellevue Hospital Medical College.

THE SMALL-POX IN MONTREAL.

Neither the small-pox itself nor the unpleasant incidents of its outbreak can be said to have shown any amelioration in Montreal. The Mayor of the city, having been intemperately accused in one of the newspapers of barbarous and inhuman conduct in enforcing the ordinance under which a certain child was forcibly taken from its home, in spite of its father's resistance, and carried to the hospital, that officer has brought suit for libel against the newspaper. While it may conscientiously be questioned how far, in the absence of a criminal charge, the sanitary interests of a community justify a forcible violation of the sanctity of the household, it is certainly unfair to hold an official up to abuse, and virtually egg on popular vengeance upon him, for simply executing the law. The sympathy of every right-minded person, therefore, whatever he may think of the abstract right of the matter, will certainly be with Mayor Beaugrand in this affair.

"THE DOCTOR'S LOST WATCH."

Under this heading one of the New York newspapers—one, too, that is generally careful not to offend against decency—publishes what purports to be a detective's story of his having tracked a thief who stole a watch from a well-known New York surgeon. Although no names are mentioned, hundreds of New Yorkers must have had no difficulty in recognizing the personality of the doctor, who, we may well believe, must resent this sort of notoriety. But, worse than that, the story plainly indicates to almost as many people who the culprit was, and thus, without the formality of a judicial investigation, consigns him to disgrace, and wantonly exposes the family affairs of his father, a most worthy citizen.

PUBLIC VACCINATION IN NEW HAVEN.

The Selectmen of New Haven, having taken in charge the business of providing for public vaccination, are reported to have determined upon doing so on what they term "business principles," *i. e.*, buying the cheapest vaccine and hiring the cheapest doctors to use it. The physicians of the city very properly resent this sort of action, and certainly nothing but downright luck can prevent its proving disastrous. It is well to remember that anything that is worth doing at all is worth doing well.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Fourth Division of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 10, 1885:

DISEASES.	Week ending Nov. 3.		Week ending Nov. 10.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid fever	39	9	23	6
Scarlet fever	34	5	20	5
Cerebro-spinal meningitis	4	5	1	1
Measles	5	1	5	1
Diphtheria	51	18	56	25
Small-pox	2	0	8	2

The Health of Foreign Cities.—We are indebted to the secretary of the National Board of Health for the following abstract of reports from our consuls, received at his office since the date of the last bulletin, November 4th: *Montreal, Canada.*

—For the week ending November 4th: 233 deaths from small-pox in the city, and 89 in adjoining municipalities. *Kingston, Canada*, October 30th: Free from epidemic diseases. *Toronto, Canada.*—For the week ending October 28th: 1 death from small-pox; the first that has occurred in the city. *Havana, Cuba.*—For the week ending October 31st: 25 cases and 12 deaths from yellow fever. *Matanzas, Cuba*, October 28th: Free from epidemic diseases. *Acapulco, Mexico.*—For the week ending October 18th: No deaths from contagious diseases reported. *Callao, Peru.*—For the week ending September 19th: 1 case and 1 death from yellow fever and 1 death from small-pox. *London, England.*—For the week ending October 17th: No deaths from small-pox, it being the first week since November, 1883, in which no deaths from the disease were reported. At the end of the week 111 cases remained in hospital. *Glasgow, Scotland.*—For the week ending October 17th: 1 death from small-pox. *Edinburgh, Scotland.*—For the week ending October 3d: 1 case of small-pox reported. *Paris, France.*—For the week ending October 17th: 5 deaths from small-pox: 40 cases under treatment in hospital. *Bordeaux, France.*—For the week ending October 17th: No deaths reported from contagious diseases. *Antwerp, Belgium.*—For the week ending October 17th: 3 cases and 3 deaths from small-pox. *Cadiz, Spain*, October 17th: No cases of cholera reported since October 14th. During the week new cases were reported at *St. Mary's* and *Seville. Barcelona, Spain.*—For the week ending October 10th: 340 cases and 126 deaths from cholera. The disease is abating and becoming milder in form. *Tarragona* and *Valencia* reported free from cholera since October 1st, and it is expected that these ports will be declared clean at an early date. *Genoa, Italy.*—For the week ending October 18th: 1 case and 1 death from small-pox. *Venice, Italy.*—From October 13th to 17th: 16 deaths from small-pox. *Prague, Bohemia.*—For the week ending October 22d: 1 death from small-pox. *Trieste, Austria.*—For the week ending October 10th: 8 cases and 2 deaths from small-pox. *Riga, Russia.*—For the month of August: 1 death from small-pox. *Bombay, India.*—From July 28th to August 18th: 35 deaths from cholera. *Shanghai, China.*—From September 4th to 18th: 7 cases and 4 deaths from cholera among the floating population. It is reported that hundreds of deaths are occurring weekly among the Chinese. *Colombo, Ceylon.*—2 cases of cholera reported since September 12th. In Italy, from September 27th to October 6th, there were 1,643 cases and 754 deaths from cholera. Of these, 1,270 cases and 58 deaths occurred in the city of Palermo. In Spain, from March 4th to October 8th, there were 271,223 cases and 100,370 deaths from cholera.

The New York County Medical Association.—At the next meeting, to be held at the Murray Hill Hotel on Monday evening, the 16th inst., Dr. Austin Flint will read a paper on "The Elements of Prognosis in Bright's Disease," Dr. J. W. S. Gouley will show photographs of pathological specimens taken while the specimens were immersed in water, and Dr. E. G. Janeway will present pathological specimens.

Medical Association of Central New York.—The eighteenth semi-annual meeting will be held in Syracuse on Tuesday, November 24th. The following papers are expected to be read:

"Remedial Gymnastics," by Dr. L. A. Weigel, of Rochester; "The Rhythm of Fever," by Dr. P. D. Carpenter, of Pittsford; "Packing in Uterine Displacements," by Dr. Streeter, of Rochester; "Pneumonia," by Dr. J. H. Jewett, of Canandaigua; "The Principle of Classification of the Chronic Insane," by Dr. E. H. Howard, Superintendent of the Monroe County Insane Asylum; "Alteration of Nutrition Due to Disease of the Spinal Cord," by Dr. Edward B. Angel, of Rochester; "An Improved Self-retaining Sims's Speculum," by Dr. C. E. Darrow, of Rochester; "Report of Several Typical Cases of Pernicious Anæmia," by Dr. J. E. Smith, of Clyde; "Pessaries, their Uses and their Abuses," by Dr. A. Dann, of Rochester; "Graves's Disease," by Dr. William C. Bailey, of Albion.

By a standing resolution, all members of the county societies in the jurisdiction of the association are invited to be present and participate in the work.

The Society of Medical Jurisprudence and State Medicine held a meeting on Thursday evening. The order of business included a paper on "Compulsory Vaccination," by Dr. J. Henry Fruitnight.

The late Dr. Armor.—On Friday evening of last week a meeting was held at the Long Island College Hospital, in memory of the late Dr. Samuel G. Armor. Addresses were made by Dr. A. J. C. Skene, Dr. Jarvis S. Wight, and Dr. Francis H. Stuart, and a memorial hymn was sung by a quartet of students of the college.

The Manhattan Hospital.—A fair in aid of this institution was opened at the University Club Theatre on Monday evening. From the large attendance it is fair to infer that this deserving institution has profited handsomely by the undertaking.

The Brooklyn Training School for Nurses.—On Monday evening a class of ten young women took their diplomas. Remarks were made by Mayor Low, the Rev. Dr. McLeod, and Dr. J. C. Hutchison.

Bequests to Charitable Institutions.—The following are mentioned as among the legatees under the will of the late Mr. John P. Howard, of Burlington, Vt.: the Association for the Relief of Respectable Aged Indigent Females, in New York; the Home for Destitute Children, in Burlington; the New York Society for the Relief of the Ruptured and Crippled; St. Luke's Hospital, New York; the New York Juvenile Asylum; the New York Children's Aid Society; and the New York Orphan Asylum. It is said that about two hundred and fifty thousand dollars are to be divided between these institutions.

The Hempstead Church Restoration Fund.—We have to acknowledge a contribution of $20.00 from Dr. W. T. Lusk, and one of $1.00 from Dr. J. Leonard Corning.

The Death of Professor William B. Carpenter, of London, is announced as having taken place on Tuesday, as the result of burns caused by the upsetting of a lamp while he was taking a vapor bath for rheumatism. Dr. Carpenter was in the seventy-third year of his age. As a physiologist he was probably better known to English-speaking people than any of his contemporaries, as his writings, which were models of clearness, were largely read by the laity. Three years ago he delivered the Lowell Institute lectures on "Human Automatism," in Boston, all but one of which were published in full in this journal. By his death, although in the fullness of years, biology loses one of its brightest ornaments, and society a noble man.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending November 7, 1885.*

KINDLEBERGER, DAVID, Medical Director. Granted leave of absence to June 30, 1886, with permission to leave the United States.

WIEBER, F. W. F., Assistant Surgeon. To remain on Receiving Ship Vermont until May 15, 1886.

Society Meetings for the Coming Week:

Monday, *November 16th:* New York County Medical Association; Medico-Chirurgical Society of German Physicians; Hartford, Conn., City Medical Association; Chicago Medical Society.

Tuesday, *November 17th:* New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private): Medical Society of the County of Kings; Ogdensburg, N. Y., Medical Association; New York State Medical Association (first day—New York).

Wednesday, *November 18th:* Northwestern Medical and Surgical Society of New York (private); New York State Medical Association (second day); New Jersey Academy of Medicine (Newark); Philadelphia County Medical Society (clinico-pathological).

Thursday, *November 19th:* New York Academy of Medicine; New York State Medical Association (third day); Roman Medical Society, New York (private); New Bedford, Mass., Society for Medical Improvement (private).

Friday, *November 20th:* New York State Medical Association (fourth day); Chicago Gynæcological Society.

Saturday, *November 21st:* Clinical Society of the New York Post-Graduate Medical School and Hospital.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of November 5, 1885.

The President, Dr. A. Jacobi, in the Chair.

A Sketch of the late Dr. James Lawrence Little was read by Dr. D. B. St. John Roosa. (See the Journal for November 7th, page 505.)

Electricity as a Therapeutic Agent in Gynæcology.—Dr. P. F. Mundé read a paper on this subject, pointing out the scarcity of the literature relating to electricity in gynæcology and the extensive use to which it might be put with benefit in various affections, many of which yielded better to this mode of treatment than to any other. One reason why he had been led to write the paper was the fact that in electricity we had an agent which could be employed by any physician with a moderate amount of skill, and which consequently offered relief to a much greater number of suffering women than methods which could be carried out only by the specialist. His experience in this manner of treating the diseases of women was based to a large extent on empiricism, as indeed was treatment by electricity in almost all affections in which it was employed. In general he had found the galvanic current of far more benefit than the faradaic. The latter had a much more restricted field of usefulness. With regard to the galvanic current, if mild it answered every therapeutic purpose, and was preferable to the powerful current which caused pain. A pleasant sensation of the skin was usually the only sensation which followed its use. The faradaic current, on the other hand, was usually beneficial in proportion to its strength. It might be taken as a rule that when the electrical current increased the pain it was doing harm, and it should be reduced in strength or discontinued. He had been unable to decide whether it made any difference, in the therapeutic results in most cases, whether the negative or the positive pole was applied externally. He had covered the pole introduced into the vagina with leather, but an electrician had told him that this made no difference; it did not offer any protection to the tissues. He usually employed the negative pole to produce an absorbent or alterative effect, using a mild current. It was well to begin with a mild galvanic current, from four to six cells, and with the faradaic current as strong as the patient could bear without discomfort, increasing the current gradually. It was well always to introduce the electrode before closing the circuit, and to diminish the strength of the current before withdrawing it, thus avoiding producing an eschar or pain. It should be borne in mind that in many cases the benefit derived from electrical treatment could only be determined after some time. An exception was where the faradaic current was employed to bring on the menstrual flow. Sittings should not take place less frequently than twice a week, and each was to be continued from fifteen to thirty minutes; it was not likely that an average of more than two patients could be treated within an hour. He could say little favorable of this means of restoring a relaxed condition of the uterine ligaments. In amenorrhœa, if there was not total absence of molimina, electricity might be found an efficient mode of treatment, and in several instances he had employed the faradaic and galvanic currents alternately with advantage. In girls, temporary absence of the menstrual flow did not necessarily call for treatment. In women who had frequently borne children, who had become plethoric, had a sluggish circulation, took little exercise, and suffered from amenorrhœa, he had found faradism, alone or alternated with galvanism, a reliable emmenagogue. Frequently several sittings were required to bring on the flow. In subinvolution and menorrhagia the faradaic current was especially indicated. In hyperplasia uteri he relied upon the galvanic current, frequently repeated and long continued, for diminishing the size and hardness of the uterus, and for relieving reflex neuroses. In "superinvolution" of the uterus, of which he saw but little, the electrical treatment would be the same as in amenorrhœa, the object being to restore the uterus and ovaries to their normal activity and growth. In pachysalpingitis electricity and other palliative methods should first be resorted to, as they would give temporary relief, and time would be given in which to decide as to the necessity for extirpation of the ovaries and tubes. In pelvic lymphangitis, chronic pelvic cellulitis, and pelvic neuralgias, local or reflex, the electrical treatment should be by the galvanic current. When these conditions were acute or subacute, electricity should not be employed, as it would be liable to excite fresh exudation. In neuralgic dysmenorrhœa, without great obstruction to the menstrual flow, he had produced benefit, after trying other means in vain, by intrauterine galvanization, employing the negative pole internally. In uterine displacements, greater improvement would probably follow the faradaic current in flexions than in versions, for electricity exerted little influence upon the elongated uterine ligaments. In fibroid tumors of the uterus electricity had a future, but, as to ovarian tumors, laparotomy was safe and reliable.

The following were some of the author's conclusions: 1. Electricity locally applied was a valuable agent in gynæcological practice, and should be more widely used. 2. It did not require great experience to be able to use it efficiently in gynæcology. 3. Correctly used, on proper occasions, it could do no harm. 4. It should be used only in chronic conditions; the galvanic current should not cause pain. 5. The faradaic current was indicated where there was deficient development or want of tone in the genital organs. The object of the faradaic current was to stimulate the organs to increased growth and activity. 6. The galvanic current was employed to promote absorption, to allay pain, to excite retarded action, and occasionally as a caustic. The use of the galvanic cautery, however, was not discussed in the paper. 7. Perseverance with the treatment was necessary to success. 8. Subacute and acute affections generally contra-indicated the employment of elec-

tricity. 9. This treatment was often successful when other forms of treatment could not be borne by the patient. Finally, in some conditions in which we could hardly hope for a cure, electricity would give great relief from pain and temporary improvement without causing danger or discomfort to the patient.

Dr. Freeman, of Brooklyn, said his experience coincided in nearly every particular with that of the author. He had employed electricity in gynæcological practice for twenty years, first using the faradaic current, then the galvanic, and during the past four years static electricity. Static electricity was much more conveniently applied, especially as it did not involve the necessity for disrobing. One of the greatest advantages of electricity was its power to allay pain; in many cases it could be substituted for opiates. In many instances patients who were suffering from pain were relieved almost immediately after occupying the insulated chair. With regard to fibroid tumors of the uterus, the author had mentioned one of his cases. In another the tumor was in front of the uterus, the needle connected with the electrode was driven into it through the abdominal wall while the patient was anæsthetized, and a current from thirty-two cells was passed during little more than half an hour. There was no severe reaction, but, owing to the delicate condition of the patient, a second application was postponed a month or longer, when the tumor was found greatly softened. There were three applications altogether, and four months after the first one the patient was able to attend to her household duties, the tumor having almost entirely disappeared. The speaker also related another case of fibroid tumor treated successfully in this manner, and said he had several others under progress at present.

Dr. A. D. Rockwell could confirm in very great part the statements made by Dr. Mundé. While electricity was not a panacea, it had a wide range of usefulness. But it needed to be employed with care. He supposed that in subinvolution of the uterus the galvanic current would be more serviceable than the faradaic. He could not see how any gynæcologist could get along without electricity in the treatment of pelvic cellulitis.

Dr. H. J. Garrigues could not speak from great personal experience, but he had employed electricity to a limited extent during the past thirteen years, particularly in amenorrhœa. But even here, and in cases of a functional nature only, it did not always fulfill his expectations; something which acted in merely a mechanical way would probably do as well. He had found that the galvanic current was liable to cauterize the vagina, even where no more than six cells were employed.

Dr. W. R. Birdsall, speaking from a general rather than a gynæcological experience, thought that what was said with regard to this therapeutic agent in most books was unsatisfactory, if not mystifying. Much better results would be obtained if more exact methods were employed. For instance, it was important to know the exact strength of the current passed. While most physicians might be able to employ it with advantage, it was still true that, the greater the skill and experience, the more likely would be the success. Among the contra-indications to the use of electricity were acute and subacute forms of disease. The effects of electricity, particularly of the faradaic current, were transient, and the applications should be repeated frequently.

Dr. Malcolm McLean thought electricity should be tried more thoroughly in cases supposed to call for Tait's operation. He laid stress upon this point because probably at least fifty per cent. of the so-called cures after Tait's operation were only temporary.

Dr. H. J. Boldt had effected a permanent cure by the alternate use of faradaic and galvanic electricity in two cases of metrorrhagia and subinvolution of the uterus in which trachelorrhaphy had failed.

The President remarked that the importance of a paper upon this subject was evident from the fact that the three latest works in German on diseases pertaining to women failed to mention the word electricity.

The discussion was closed by Dr. Mundé, who said that several of the points raised in the discussion had been dwelt upon in the paper, but the lateness of the hour had induced him to pass them by.

The President announced that, owing to illness, Dr. Janeway would be unable to read the anniversary address at the second meeting in November, and that Dr. H. D. Noyes had kindly consented to act as orator on that occasion.

NEW YORK SURGICAL SOCIETY.

Meeting of October 27, 1885.

The President, Dr. Robert F. Weir, in the Chair.

A Simple Fracture of the Patella treated by Wiring the Fragments; a Second Fracture treated by Suturing the Fragments with Catgut.—Dr. L. A. Stimson presented a man, twenty-one years of age, in whom he had had the opportunity of observing the condition of the knee joint two months and a half after the patella had been wired for a simple fracture. The patient came to Bellevue Hospital last June with simple fracture of the patella, and was treated by one of Dr. Stimson's colleagues by making a transverse incision and wiring the bone with silver wire, two sutures being inserted. The case did perfectly well, and the patient recovered without any elevation of temperature or manifestation of trouble in the joint. When Dr. Stimson first saw him, two months and a half after the operation, the fragments were closely united, without independent mobility, and the patient was walking about the wards with a condition of the knee which allowed the joint to move through the arc of a circle of about 20°. About one week afterward, while descending the stairs without falling, stepping down with the sound leg forward, he fractured the patella which had been broken. Previous to the accident Dr. Stimson had noticed what seemed to be one of the wire sutures which could be felt under the skin, and the patient had felt a slight pricking pain at that point throughout the progress of the case. In the second fracture the old cicatrix was torn open. Dr. Stimson enlarged the wound, and found that the second fracture had taken place exactly in the line of the first; one wire was entirely, the other almost entirely, loose in the wound, and the site of each was marked by small cavities in the fragments. The surfaces of fracture were not so rough as usual, and Dr. Stimson thought that union had taken place, in part at least, by a very thin intermediate layer of fibrous tissue. On the inner corner of the upper fragment, where in the first fracture there had been a small loss of tissue, there was a distinct fibrous band, as large as his little finger. On wiping out the blood he saw a membrane of new formation underlying the patella, and entirely separating the fracture from the cavity of the joint, except at one point, where it was torn for half an inch; through this opening he was able to see false membranes within the joint connecting the condyles of the femur with the tibial head. He cleansed the wound, brought the fragments together with catgut and closed the wound, and the patient was now well. The fragments had again united, and there was some mobility in the joint. It was now two months since the second fracture. The reason Dr. Stimson reported the case was because he had seen not long ago the statement that there was no case known where any membranes of new formation had formed in the joint after wiring of the patella for simple fracture. But this joint was full of them, and they had formed without any inflammatory reaction or any symptoms indicating their formation. Again, it has been stated

that a patient with a fracture of the patella treated by wiring could be dismissed cured at the end of four weeks. Dr. Stimson did not know of any other similar fracture which was perfectly sound at the end of so short a period of time, but here was a case in which two months and a half had elapsed since the fracture, which had done well, and which, if reported two or three months ago, at the stage at which most cases had been reported, would probably have been cited as another example of the safety and value of the method of treating by wiring, and yet the union proved not to be strong enough to bear the weight of the body in descending stairs, and the joint did not allow of more than 20° or 30° of flexion.

Dr. C. K. Briddon asked if catgut had been used for this purpose before.

Dr. Stimson said he had used it several times in operations upon joints. He thought it would last probably three weeks.

Dr. W. T. Bull asked what the ultimate prospect was, so far as motion was concerned in this joint.

Dr. Stimson answered that it was poor.

Dr. Bull asked if that was not generally true in cases in which the patella was wired.

Dr. Stimson had not seen good motion in any case, but it had been reported that the operation gave good motion.

Dr. A. C. Post asked whether, if the choice was between a stiff and a weak joint, the stiff joint was not to be selected.

Dr. Bull thought it was.

The President asked if it was not true also that, after fracture treated by the ordinary method, better results were obtained than in the joint of the patient presented.

Dr. Stimson replied that a good deal better results were obtained.

Tubercular Disease of the Tarsus; Resection of the Astragalus and Scaphoid Bone.—Dr. Bull presented a young woman in order to show the result of an operation which had been performed eighteen months before. She presented herself at the New York Hospital on the 17th of March, 1884, with the history that she had been in somewhat delicate health, having had cough but no hæmoptysis. Seven weeks before admission she complained of lameness in the right foot and inability to walk without considerable pain. The motions of the ankle were nearly perfect. The only evidences of disease of the bones of the tarsus were a decided tenderness over the scaphoid and a slight swelling below the ankle, and, besides, there was atrophy of the calf upon that side, which was one inch smaller than its fellow. For seven weeks the foot was treated with a plaster-of-Paris splint and applications of oleate of mercury, Paquelin's cautery, belladonna liniment, etc., without improvement. Dr. Bull then made an incision upon either side of the ankle and removed the astragalus and the scaphoid bone. He did not detect any indications of tubercular disease of the synovial membrane, but the bones were softened. They were removed entirely with knife and scissors. The wounds healed promptly, with the exception of the sinuses left by the drainage-tubes, which were somewhat slow in closing. In about a month she was able to walk about and bear some weight upon the foot, but with considerable pain. Five months later he discovered a good deal of tenderness over the os calcis and suspected similar disease of that bone, and, although the motions at the ankle joint were quite good, he introduced a drill by means of the dental engine into both malleoli, and also into the os calcis. In the former he found no evidence of disease, but in the latter he found a soft spot, which he drilled out and treated with iodoform, and it healed promptly. This operation was performed eight months after the first one, and since that time the pain in the ankle and foot had gradually disappeared. Now the functions of the foot seemed to be perfectly performed, and the only deformity was a shortening of the foot by about one inch. The calf of the leg had increased in size until it was only half an inch smaller than the other. Unfortunately, as regarded a positive diagnosis, the bones were lost and therefore not examined for micro-organisms, but, although they did not present to the naked eye any of the characteristic appearances of tubercular lesion, Dr. Bull felt warranted in believing that the disease was of that nature. It might be remembered that at a meeting of the society last spring he had presented a patient, an Italian, from whom he had removed the entire tarsus for tubercular osteitis. The result had not seemed to be satisfactory, as the man experienced some pain in walking. His condition had improved materially since that time, and he was able to do all sorts of active work without discomfort.

Dr. H. B. Sands thought that the results in cases of excision of the tarsal bones were usually better than might be anticipated; and the observation made by Dr. Bull, that the patients continued to improve for a considerable period after the operation, accorded with his own experience. In cases of tubercular disease of the joints in which operations for the removal of a diseased bone were performed by means of a sharp spoon he supposed that frequently a sufficient amount of periosteum was left to reproduce, to a considerable extent, the bone removed, and in this manner to contribute to the stability of the foot. He had repeatedly noticed, after thus dealing with the tarsal bones, and also after removal of the carpal bones, that, although a large portion of osseous tissue was removed, after the lapse of six months or a year the parts became so firm that one could hardly believe that such an amount of bone had been taken away.

Dr. C. T. Poore said that, in cases occurring in children where he had endeavored to remove the os calcis and leave a portion of the bone with the periosteum, he had subsequently been obliged to remove the entire bone because of non-closure of the wound, and because the disease was extending to other bones. In one case he had been certain that he left the anterior portion of the bone undisturbed. Eight or nine months after the first operation he found the cavity, as it were, of the os calcis filled with dense fibrous tissue. In children he had not been able to save any of the bone, but had removed everything, and the results had been very good.

Stricture of the Œsophagus; Internal Œsophagotomy.—Dr. Sands presented a woman, twenty-one years of age, who had come under his observation one year ago last June. She was sent by Dr. Paddock, of Dalton, Mass., on account of a stricture of the œsophagus, which was the result of the accidental swallowing of a solution of caustic potash when she was two years old. Dr. Paddock stated that he had been called to see the patient on account of dysphagia, and that she was unable to swallow solid food, and was badly nourished. He detected a close stricture through which he could pass only the smallest bougies. When she came to Dr. Sands he was able to confirm the diagnosis made by Dr. Paddock, and found a stricture situated seven inches from the incisor teeth, through which he could introduce a French catheter, No. 12. He endeavored to dilate the stricture, and succeeded in carrying the dilatation up to No. 23 French, but was unable to accomplish more. Therefore, on the 9th of July, 1884, he introduced the œsophagotome which he had already shown to the society, passed the bulb beyond the stricture, projected the blade 2·5 mm., and then withdrew it, making an incision in the posterior median line of the œsophagus. Immediately after the operation, which was performed without an anæsthetic and was attended by no hæmorrhage, he passed a No. 29 (French) bougie. Subsequently he carried the dilatation up to No. 34 (French). After the cutting operation, instruments were at first passed every second or third day, and during the summer and autumn at in-

tervals of three weeks. In December the interval between the introductions of the bougies was increased to one month, after the 1st of January to two months, and now there had been an interval of three months, without any diminution in the caliber of the œsophagus at the point where it had been divided. Soon after the operation, exploration of the œsophagus revealed the presence of another stricture, ten inches from the incisor teeth, which admitted a No. 24 (French). Dr. Sands dilated this stricture, and carried the dilatation up to No. 29, but beyond this he had been unable to dilate it. He then demonstrated the lower stricture, and showed that the upper stricture allowed a bougie No. 34 to pass, while the lower one arrested instruments larger than No. 29.

The reason why he presented the patient was because he thought it desirable to correct the common impression that all strictures of the œsophagus exhibited an invincible tendency to recontraction, and that the operation of internal division was unsatisfactory because it was not likely to produce any permanent good result. It so happened that he had received this evening a communication from the friends of a child upon whom he had performed several operations of internal œsophagotomy two years ago, for the relief of a stricture of the œsophagus, and whose case he had already reported to the society. In that instance dilatation was carried up to No. 29. The child improved in health, was able to eat solid food, and had remained well ever since. At the present time she swallowed as well as other children, yet no bougie had been passed since last May. Dr. Sands cited these facts in order to prove that internal œsophagotomy might sometimes produce results which were permanent; and that, although the œsophagus might not be restored to its normal dimensions, it did not necessarily tend to contract below such dimensions as would permit of easy deglutition. He had been led to desist from doing more in the case of the patient exhibited this evening, because she was in good health, had increased in weight from ninety-six to one hundred and nine pounds, and was able to swallow liquids without difficulty, and, with care, to swallow solids when well masticated.

Strictures of the œsophagus closely resembled strictures of the urethra, in which there were found every grade of constriction and also a vast difference in the amount of tissue which caused it. He had seen a case of stricture of the œsophagus in which the entire tube was converted into a rigid canal. Under those circumstances no operation whatever could succeed in restoring a fair amount of dilatability of the œsophagus; but he believed that, in many cases, strictures were limited to a very short part of the canal, and in those cases he imagined that internal œsophagotomy would be likely to be followed by the greatest relief with a minimum amount of risk.

Dr. Stimson asked why a further operation was not done upon the lower stricture in the patient presented.

Dr. Sands replied, only because it seemed already large enough to allow of the easy deglutition of masticated food, and also because it had not shown any tendency to contract below the caliber of No. 29. He was, moreover, inclined to refrain from cutting the lower stricture, for the reason that it was related to more important parts than the upper one; therefore any accident in the operation might be more serious in its results. He imagined that the caliber of the œsophagus might be restored to its normal size, but he did not feel warranted in doing more than seemed absolutely necessary to render deglutition easy.

Dr. Bull had had occasion to treat one patient, a lady, who entered the New York Hospital two years ago. The stricture was about ten inches from the incisor teeth, and depended, so far as could be determined, upon a severe sore throat, possibly diphtheria. It was only with great difficulty that the patient could swallow anything except water. The stricture admitted only a No. 8, possibly No. 10, French. By persistent gradual dilatation the stricture was stretched until, at the end of four months, it admitted No. 32 or No. 34, French. Dr. Bull saw the patient up to one year afterward. The bougie was passed at short intervals during four months, and at intervals of a month during the remainder of the year, at the end of which time the condition of the œsophagus was perfectly satisfactory, as the patient could eat anything which she chose.

Congenital Angioma.—Dr. Charles McBurney presented a man who had a congenital angioma of unusual size upon the right side. The tumor was five inches in breadth and four in depth, and extended from the median line in front to within three inches of the median line behind. The patient stated that during early youth and until within the last seven or eight years the tumor had bled regularly, and that he had lost large quantities of blood, sometimes as much as a quart at a time. During the last seven or eight years he had been very comfortable, with firm compression of the growth, and had had no hæmorrhages. Dr. McBurney felt inclined to advise him to continue with this treatment, and not to have any operation whatever performed. The tumor was not pulsating at any part, was venous, and was of the cutaneous and subcutaneous variety, chiefly the latter.

Epithelioma of the Tongue; Removal by Kocher's Method.—Dr. Stimson presented a specimen of epithelioma of the tongue, for which he had removed almost the entire organ by Kocher's lateral supra-hyoid method. The patient was a man sixty-eight years old; the disease extended as far back as the finger could reach through the mouth, and involved the floor of the mouth and the gum on the right side from the median line two inches backward. On the dorsum of the tongue there was a very large irregular ulcer. Tracheotomy was done, and the etherization was continued through the tube. The incision was made on the right side, and the right lingual and facial arteries were tied in the wound before their division; the left lingual was tied through the wound after its division, and this was the only ligature that was made necessary by the removal of the tongue. The entire organ, except a strip of mucous membrane at its base, was removed, as was also a portion of the submental muscles which had become involved in the disease. The area of raw surface created by the removal was diminished by drawing the adjoining mucous membrane over it so far as possible and stitching it fast. The wound was packed with iodoform gauze, and the mouth frequently cleansed with a solution of salicylic acid and borax, and the patient had been regularly fed through an œsophageal tube. The tracheotomy-tube was removed on the sixth day. The patient was now, on the sixteenth day, doing well.

Dr. Sands had within the last ten days had occasion to remove the lateral half of the tongue on account of a cancerous swelling situated on the left side of the organ, extending toward the root but not to the median line. He adopted the method known as Whitehead's. He etherized the patient, introduced Wood's mouth-gag, passed a stout ligature through the tongue upon the right side, drew it forward, divided with a pair of straight scissors its attachments to the lower jaw and to the floor of the mouth, split the tongue in the median line toward the root, then made a transverse cut, dividing the tongue and the anterior pillar of the soft palate, and completed the operation with the loss of only about eight ounces of blood. He had but little difficulty in applying a ligature to the lingual artery. He packed the wound with gauze, and used a small stomach-tube for feeding the patient during the first week. The progress of the case had been entirely satisfactory, the man was now

able to swallow, and was convalescent. Dr. Sands was very much impressed with the excellence of the method in those cases in which the disease was strictly limited to the tongue. He was sure that the operation could be safely done if the entire organ required to be removed, and he should prefer to perform this operation rather than that which included a preliminary ligation of one or both lingual arteries.

Dr. Briddon asked if the difficulty in securing the arteries would not be greater in Whitehead's operation.

Dr. Sands replied that the operation did not consist in cutting off the tongue at once, but in making short strokes and tying the arteries as they were divided. Of course the cases should be selected in which the operation was especially applicable.

The President remarked, with regard to Kocher's operation for removal of the tongue well back, that it had pleased him most on account of the thoroughness with which all diseased tissue could be removed.

Necrosis of the Os Brachii without the Formation of an Involucrum.—Dr. Post presented a specimen of necrosis of the os brachii without any attempt at the formation of an involucrum. It was removed from a boy twelve years of age, with the history that between one and two years ago he was bitten by a spider, and that the bite was followed by very severe inflammation. A number of months afterward extensive suppuration occurred about the joint, and Dr. Post performed excision of the elbow. Subsequently he found that the wound at the joint had healed, but that there was suppuration higher up, with loss of continuity in the bone of the arm nearly as high as the middle. Recently he cut down upon the bone and found that its lower extremity was necrosed to the extent of 65 mm. on one side and 35 mm. on the other. The dead bone was lying loose in the midst of granulations. The inferior extremity of the living bone above presented a jagged extremity, but was not bare to any considerable extent. He did not remember any other instance in which necrosis of a long bone of an extremity had occurred without the formation of an involucrum, except in a case of necrosis of the fibula, also in a boy, in which the tibia was not involved. In that case the fibula, for its whole length except the two articular extremities, was in a state of necrosis, and there was no involucrum. The tibia formed a support for the limb, so that there was no false point of motion.

Dr. Stimson thought that something besides simple necrosis had occurred in the bone presented, as it was filled with bony deposit, and that the shell had disappeared by absorption.

Dr. Post remarked that the whole process was different from the ordinary process of necrosis, but the bone was evidently dead.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting of October 6, 1885.

The President, Dr. W. R. Birdsall, in the Chair;

Dr. G. W. Jacoby, Secretary.

Dr. M. A. Starr, Dr. I. Adler, Dr. J. B. Emerson, Dr. R. M. Cramer, and Dr. R. G. Wiener were elected to membership.

A Contribution to the Pathology of Hemianopsia of Central Origin.—Dr. E. C. Seguin read a paper with this title. He first gave a brief synopsis of views, anatomical and pathological, of hemianopsia of basal or peripheral origin, recognizing the following types: 1. Horizontal hemianopsia, superior or inferior, usually due to lesions within the eye, and hence of comparatively little interest to the neurologist. 2. Vertical hemianopsia, always caused by a lesion of the basal visual apparatus or by disease in a certain limited part of the cerebrum. Its varieties were: *a*. Temporal hemianopsia, in which the temporal half of both visual fields was dark. *b*. Nasal hemianopsia, in which the nasal half of both visual fields was obscured. *c*. Lateral hemianopsia. This was often designated homonymous hemianopsia. In this variety the nasal half of one visual field and the temporal half of the other were dark, so that, with one or both eyes open, the patient saw the same half of any object placed in front of him. This variety was the one which resulted from a truly central lesion, and formed the subject of study in the paper. Varieties *a* and *b* were caused by lesions variously placed in or around the chiasm of the optic nerves.

The author proceeded to analyze the recorded observations of hemianopsia due to cerebral lesion, forty-two in number, including his own case. Of these, thirty-seven were medical and accompanied by autopsies; five surgical, followed by survival of the patient. These relatively numerous observations were classified as follows: A. Cases of lateral hemianopsia, indefinite or irrelevant, and useless for localization study, fifty-four in number; observed by Charcot and Pitres, Linnell, Wiethe, and Petrina. B. Cases of lateral hemianopsia from lesions of parts of brain not directly related to the optic apparatus, three cases; by Hirschberg, Huguenin (obs. of 1876), and Pflüger. C. Cases of lateral hemianopsia from lesions involving chiefly the thalamus opticus or corpus geniculatum laterale, six in number; by Jackson and Gowers, Pooley, Dreschfeld (three cases), and Rosenbach. D. Cases of lateral hemianopsia from lesions chiefly or exclusively involving the white substance of the occipital lobe, eleven cases; by Levick, Hosch, Baumgarten, Dmitrowsky and Lebeden, Westphal (1881), Senator, Sturger (Case vii), Wernicke and Hahn, Jany, Richter, and Schmalz. E. Cases of lateral hemianopsia of external or traumatic origin, five cases; by Keen and Thomson (re-examined by Dr. Seguin), Hughes, Schmidt-Rimpler, Heuse, and Nieden. F. Cases of lateral hemianopsia due to lesions involving the cortex of the brain and subjacent white substance, thirteen cases; by Westphal (1882), Stenger (Case viii), Förster and Wernicke, Jastrowitz (two cases), Cnrschmann, Nothnagel, Marchand, Chaillou, Haab, Huguenin (1882), Féré, and the author.

This last category being by far the most important for the study of the localization of the visual center in man, Dr. Seguin gave full abstracts of all these cases. The lesions in all were so placed as to cumulate toward the mesal aspect of the occipital lobe. This result was shown by means of a shaded chart, consisting of a diagram of the mesal and lateral views of the brain, upon which the lesions of the thirteen cases were reproduced and with one layer of India-ink. The result was striking, visible in the greatest blackness of an area upon the mesal aspect of the cerebrum, including the lower part of the cuneus and the fifth temporal gyrus (Ecker). To this locality also was limited the lesion found in the following cases: Haab's, Huguenin's, Féré's, and Seguin's. These were single lesions, and no paralysis or anæsthesia had been observed during the patient's life—only hemianopsia.

Dr. Seguin's own case was as follows: A man, aged forty-six, affected with malignant endocarditis (mitral vegetations) which proved fatal in sixteen months from first observation, in January, 1884, through repeated visceral embolisms. This patient also exhibited for many weeks an exquisite intermittent form of fever, closely imitating malarial intermittent. About December 5, 1884, Mr. D. suddenly complained of "blindness of the left eye," and slight numbness through the whole left side of the body. He strongly insisted then, and frequently thereafter, that his left eye was alone affected, because he could not see to his left. Examination showed well-defined left lateral hemianopsia, the vertical line passing a little to the left of the point of fixation. In a short time the numbness passed away, but the hemianopsia persisted until death. For many months before death Mr. D. was able to read

and write easily and attend to business outside, in spite of the hemianopsia. The lesion found at the autopsy was a large old patch of yellow softening, involving the greater part of the right cuneus (almost reaching the apex of the occipital lobe) and the fifth and fourth temporal gyri, extending also frontad into the gyrus hippocampi. This lesion was found to be due to a blockade of the occipital branch of the posterior cerebral. The white matter was involved to a depth of several millimetres. No sections were made in the fresh state of the specimen, in order to prepare it for more careful examination when hardened. Unfortunately, this process was unsuccessful in part, and only the occipital end of the brain became hard. The absence of decided motor and sensory symptoms during life, however, made it quite certain that there were no other gross lesions in the brain.

From these four cases, supported by the cumulative evidence of all the others, Dr. Seguin considered it well proved that the visual center (receiving impressions from one corresponding half of each retina) in man was in the cuneus and adjacent gray matter below it. A destruction of this part of the hemisphere inevitably produced lateral hemianopsia of the field on the opposite side of the body. As regarded those few cases in which the lesion causing lateral hemianopsia was situated upon the lateral aspect of the hemisphere, in the inferior parietal lobule and the gyrus angularis, Dr. Seguin called attention to the fact that the optic fasciculus of Gratiolet and Wernicke on its way from the primary optic centers, laterad of the posterior horn of the lateral ventricle, to the cuneus, passed close under these gyri, and a lesion which penetrated at all beneath the gray matter of their cortex must intercept the optic fibers, by pressure or by destruction. These were lesions intercepting communication between the eyes and the visual center, while lesions of the mesal aspect of the occipital lobe destroyed the center itself.

Dr. T. R. Pooley, without knowing at all the direction which Dr. Seguin's paper would take, had hastily looked over his records before coming to the meeting, and briefly abstracted five cases of hemianopsia of which he had notes. One of these cases had been referred to in the paper. The speaker felt quite incompetent to discuss the physiological and theoretical question as to the location of the lesion, and the importance of different symptoms in helping to exactly locate the lesion in the brain. He had intended to relate clinical histories somewhat in detail, but would content himself with speaking only of one case, which had recently come under his observation and in which the patient was now under treatment. It was one that he had seen a week before—that of a gentleman, aged thirty-five years, who had been under his care in 1879 for comparative blindness of his left eye, which had been found to be due to circumscribed choroidal exudation situated near the macula lutea. From his former observation of such cases, the speaker had always believed them to be due to syphilitic infection, and careful inquiry into the history of this case showed it to be due also to this poison. The patient remained for a time under treatment for this inflammatory exudation, from which he recovered with a scotoma, and enjoyed comparatively good health and freedom from all further syphilitic manifestations until a week ago, when he consulted the speaker again. On this occasion he was driving with his wife in the country when he suddenly became completely blind. This blindness lasted only a few moments. Upon recovering, he ascertained that there was dimness of vision upon the left side, which continued when he came to see the speaker. Examination showed left homonymous hemianopsia, the blind area extending almost to the point of fixation in each eye. Examination of the acuteness of vision showed that of the left eye (and this was interesting because of the previous condition of that eye) to be $\frac{22}{100}$, that of the right eye being $\frac{20}{20}$, or perfect. The optic discs were quite normal, the blood-vessels were of full size, and there was no indication of atrophy of the optic nerve by neuritis. The interesting and remarkable fact in this case was the improvement which took place within a week from the commencement of treatment. On account of the previous history of the case, the patient was given large doses of iodide of potassium. The first day after treatment had been begun the visual fields had increased in extent, and this increase had steadily continued until the present date. Unfortunately, there had been no opportunity to make measurements with the perimeter, the patient being treated at his home, but the speaker estimated that the field of vision had extended from near the point of fixation to one third the normal limits, the increase being apparently symmetrical. He would like very much to have Dr. Seguin's opinion as to whether in a case of this kind, in which there had been such marked improvement within a week, we might hope for permanent benefit.

Dr. M. A. Starr thought that the list Dr. Seguin had presented was a complete one with perhaps a single exception, that of a case reported by Demange, in the "Revue de médecine" for May, 1883. That case was referred to by Dr. Gowers in his last work on diseases of the brain in a way to lead one to suppose that it supported the assertion of Ferrier that the angular gyrus was the center for vision. The speaker had found, however, on looking up the case, that the lesion was one which coincided very largely with that of Westphal's first case, and it was very well represented by the diagram of that case shown by Dr. Seguin. It was a very large lesion, involving both parietal lobules and the occipital lobe. Gowers referred to that case as proving that a lesion upon one side of the brain might produce blindness of the opposite eye, and said it supported Ferrier's assertion of amblyopia being due to lesion of one angular gyrus. In the original report, however, it had only been stated that the patient could not see well with the left eye, and not that there had been any careful measurement of the field of vision. Therefore in all probability the patient had hemianopsia, and, as in a number of cases reported by Dr. Seguin and in a number which the speaker had collected, from lack of careful observation, the examining physician had failed to elicit the symptom which was undoubtedly present. The necessity for careful examination in all these cases had been dwelt upon by Dr. Seguin, and it ought to be emphasized, because it was evident from the histories of these cases that a patient with hemianopsia did not notice the exact field of vision, but only noticed that he was blind in one eye, and referred it to the eye of which the field of vision was the more largely implicated. The necessity for such an examination was shown in the fact that Dr. Seguin had been able to collect eight cases in addition to those which the speaker had collected, so that eight new cases had occurred since January, 1884. This great increase in the number of cases of hemianopsia was only apparent, few cases having been recorded previously because of imperfect examinations of the visual field. He would not anticipate Dr. Seguin in answering the question asked by Dr. Pooley, but he had in hand a case, published by Baer in Volkmann's "Sammlung klinischer Vorträge," which was almost identical with that related by Dr. Pooley this evening—a case of hemianopsia coming on suddenly in a syphilitic individual. A series of diagrams was given, showing the progressive improvement of the patient and his final complete recovery. The speaker's attention had first been called to this subject three years ago by seeing a case of hemianopsia in Charcot's wards, and in his lecture on that case Charcot virtually retracted his own diagram and adopted one like that shown by Dr. Seguin. So that we should cease to copy the old diagram made by Charcot, as it had been abandoned in France and Germany. The absolute necessity for such a collection of cases as Dr. Seguin had made, for settling any disputed question of localization, was perfectly evident. It was the only way in which this question

of localization could be really determined. To draw conclusions from physiological experiments was no longer warranted. We must go to carefully-made autopsies. It might be interesting to know that in October, 1858, the Pathological Society of Philadelphia discussed the subject of abscess of the brain, and that at that meeting Dr. Weir Mitchell presented a case, with the records, in which a large abscess at the posterior part of the brain, involving both occipital lobes, was attended with blindness, and the blindness seemed to be the chief *local* symptom (as we should say now) of the disease. The Pathological Society was at a loss to explain the occurrence of blindness with this lesion in the occipital lobes. It was encouraging to the general cause of clinical diagnosis that now, after the lapse of these years, we were able to explain perfectly the case which then so puzzled that society.

Dr. Seguin closed the discussion with reference to Dr. Pooley's question. He could not answer it, for want of experience. He had never seen a case of hemianopsia which was not embolic, or possibly due to a tumor, in which there was no indication for treatment.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Meeting of October 19, 1885.

The President, Dr. Charles A. Leale, in the Chair.

Fracture of the Patella.—Dr. Frederic S. Dennis read a paper in which he weighed the arguments for and against wiring of the separated parts of the fractured patella. Surgeons were divided in opinion with regard to the merits of this method of treatment, some maintaining that it was perfectly justifiable, and, under strict antiseptic precautions, free from danger. On the other hand, it had been said that, previous to 1883, two cases had terminated in death and several in ankylosis. But a study of the statistics since 1883 showed a great diminution in what was then a small mortality, and a great decrease in the number of cases which had resulted in suppuration and ankylosis. Dr. Dennis had collected about twenty-three cases since 1883, exclusive of those which had occurred in Bellevue Hospital. According to a general estimate there were as many as fifty cases, and in none, so far as could be ascertained, had death occurred after this mode of treatment if but a simple fracture existed. In three of the fifty cases suppuration occurred, but one of the three was a case of compound fracture. In this, as in all other important operations, failure would occur now and then, even in the hands of the most skilled and circumspect surgeons. Those who opposed the operation based their opposition on a supposed risk of opening the knee joint and on the assumed fact that equally good effects could be obtained by less heroic means. As to the good results alleged by those who advocated older methods of treatment, careful analysis of a large series of cases proved that, as regarded the condition of the joint and the character of the union, they were unsatisfactory; that they were much inferior to the excellent results obtained by the use of the metallic suture. During the last five years Dr. Dennis had treated sixty cases of fracture of the patella, and until recently had used old appliances, particularly plaster of Paris as it was employed by the late Dr. Little. The results in the great majority of cases had been unsatisfactory, particularly as contrasted with those obtained by wiring the fragments. That bony union was possible, however, without the suture, was evident from a specimen presented. When Sir Joseph Lister was asked why he wired the fractured patella, he said his first reason for doing the operation was that it relieved muscular spasm in the quadriceps, and the second that it permitted the escape of blood from the joint. In the debate it was asserted that tenotomy would accomplish the first object, and aspiration the second. Sir Joseph then replied that it was because he had such faith in his antiseptics. A more substantial and cogent reason would be that the operation was comparatively free from danger, and, while it relaxed muscular spasm and permitted of the escape of blood from the interior of the joint, insured in every case osseous union of the fragments, and, as a natural consequence, unrestrained movement in the joint. The reason why osseous union was not obtained when the wire was not employed was, that the aponeurotic fascia falling between the fragments prevented union. Until this fascia was removed from between the fragments, which could only be done by opening the joint, osseous union was not likely to occur. There were three arguments in favor of this operation as against other methods of treatment, which the author thought could be substantiated: 1, The absence of danger to life and limb; 2, superior results as regarded function of the limb and joint; 3, greater rapidity of repair. The mortality prior to 1883 was attributed to the fact that the operation was in its infancy. Since then improved methods of performing it had enabled the operator to conclude the operation in not more than thirty minutes. Formerly two hours were often consumed, principally in drilling the holes and passing the wire; now, with the Archimedean drill, the holes could be made in four seconds. No one questioned the superiority of the method over all others in cases of compound fracture. A patient was presented who had had compound fracture; no constitutional symptoms developed, and he was enabled to walk well within eight weeks; he could run up stairs and dance as well as before the injury. A specimen was presented which was removed from the body of a patient dead of delirium tremens and Bright's disease six days after a fractured patella had been wired. The joint was aseptic, there were no indications of suppuration, and bony union was sufficiently strong to have enabled the patient to walk without separating the fragments. Union did not take place by callus, but by primary intention, as it would in the soft parts. As regarded superiority of the results over those of other methods, there was no separation of the fragments, but bony union; no ankylosis, no pain, no crutches, no knee-cap, no posterior splint, no liability to refracture unless by direct violence, no fear of falling, no difficulty of locomotion, no synovitis, no œdema of the limb—none of the chapter of mishaps which were likely to happen under the older method of treatment. As to the greater rapidity of repair, by the older method nearly three months were consumed in the repair of the fracture, and two years in restoration of the functions of the joint and limb. After wiring of the fragments the patient had complete use of his limb within eight weeks, and could safely move about within three weeks. Wiring of the fragments should not be performed immediately after a simple fracture, as inflammation would be liable to result. It was better to wait a few days. After compound fracture the operation should be performed right away. Strict antiseptic precautions should be observed; Dr. Dennis employed a solution of bichloride of mercury, 1 to 3,000, and kept up irrigation during the operation. The operation should not be performed by the ordinary practitioner, nor by a surgeon who had little faith in the germ theory.

Dr. Fowler, of Brooklyn, to whose cases the author had alluded, presented some patients upon whom he had wired the patella in simple and compound fractures. In one case the separation between the fragments could not be reduced to less than an inch and a quarter until after he had resorted to the method advocated by Macewen of cutting a V-shaped piece out of the quadriceps muscle, when they were approximated with ease. Regarding the ends of the twisted wires, instead of hammering them down, he bent them between the fragments. It was better, however, to use the bridge suture and remove them

when union had been completed. He had made the holes in the fragments with a shoemaker's awl, and inserted the wire through a cannula.

Cultivations of the Micro-organisms of Osteo-myelitis were demonstrated by Dr. H. M. Biggs, who showed the *Staphylococcus cerveus albus* and the *Staphylococcus pyogenes aureus.*

Dr. J. Faure, lately of the French navy, was introduced to the society, and presented a *serre nœud* which he had invented.

Nummulites from the pedestal of Cleopatra's needle were presented by the President.

Miscellany.

The International Congress.—In its November issue, the "Pacific Medical and Surgical Journal," of San Francisco, says:

"The only important events regarding the Congress that have transpired since our last issue are the publication, in the 'American Medical Journal' ['Journal of the American Medical Association'] of a historical account of all that has been done by the American Medical Association in this matter since the meeting in Washington, in May, 1884, and the declaration of independence by the Executive Committee appointed by the Committee of Arrangements at its session two months ago. In his historical account, the editor of the 'American Medical Journal' ['Journal of the American Medical Association'] argues that, as the Committee of Invitation had been appointed by the American Medical Association, therefore the association was accountable for all acts of the said committee. If we could only agree with him in this one particular point, and be convinced of the validity of the association's claim to supremacy, he would receive our most hearty co-operation in upholding the action of that body against its assailants. Unfortunately we can not acknowledge this authority.

"The invitation was presented at Copenhagen in the name of the 'profession in the United States.' We grant it must have been known in Europe that the idea originated in the American Medical Association, and that the initial steps were taken by that body; but this information only reached them indirectly, as the name of the association was not included in the invitation, and should not therefore appear on the official records of the Congress, which constitute the only laws governing that assembly. If the association never extended an invitation, we can not see what right it has to claim the position of host on this occasion; and if the crime of being a 'first cause' is to decide the matter, then the whole responsibility for the shame and disgrace which have accrued to the American medical profession in connection with this subject must be laid at the door of that unfortunate being who first agitated it among his medical brethren. Further: According to the custom of the Congress, the gentlemen presenting the invitation for the next place of meeting have been regarded as their committee for making the necessary arrangements, and hence Dr. Billings and his *confrères*, so soon as their invitation was accepted, ceased to be the ambassadors of the 'profession in the United States'; they even, in the eyes of the Congress, laid aside their character as national representatives, and became the servants of that body, intrusted with the duty of making the necessary arrangements for the meeting of 1887, and selected for this purpose only because they were resident in the country where that meeting is (or was) to be held. We have already given the testimony of Sir James Paget and other prominent members of the Congress in support of these statements, which prove beyond a doubt that Dr. Billings's committee, after discharging their duty of presenting the invitation intrusted to them by the profession in the United States, became responsible to the Congress alone for their future actions in the matter.

"It may be objected that the duties of the committee did not end with presenting the invitation, because they had full powers *from the association* to make all preliminary arrangements. This is just the point where the American Medical Association overstepped its own authority, and interfered in a matter with which it had no business. The Congress has its own committee for making its arrangements, and the fact that the association, either through ignorance or presumption, endeavored to control this committee, does not by any means transfer the power from one to the other. This is of much importance, for the point at issue is: Has the Congress the power of making arrangements for its own meetings, or does that power lie in the hands of the American Medical Association? The Arrangement Committee is answerable to either one of these bodies, but not to both; and the one to which it is answerable has full power to approve or disapprove of its action. We have shown that hitherto this power remained in the hands of the Congress. We hoped that the committee would have recognized this fact at its meeting in September last, and courteously retired from the false position which they now hold. It is no disgrace for any one to admit that he has made a mistake, and this certainly would have brought 'peace with honor.'

"We have given this historical account of the working of the Congress to show our readers that this triennial medical convention antedates the meeting of the American Medical Association at New Orleans in 1884, and has, therefore, some laws and precedents to regulate its actions. Probably the most startling event in the whole history of this miserably-bungled affair is the following resolution, passed by the Executive Committee appointed by the Committee of Arrangements two months ago: '*Resolved*, That this Executive Committee enters upon the management of the affairs of the Ninth International Congress with the understanding that, in accordance with Rule No. 10, its powers are not restricted, except by the rules and regulations adopted September 3, 1885, by the Committee of Arrangements appointed by the American Medical Association, in April, 1885; and that the actions of this Executive Committee are final, not being subject to revision, amendment, or alteration, by either the Committee of Arrangements or the American Medical Association.' We certainly admire this bold piece of policy on the part of the Executive Committee, but hardly find it consistent with the opinion which the American Medical Association obtained from Ex-Speaker Randall, and with which they sought to justify their action at New Orleans: '. . . The theory that a select committee, created by a body with certain defined powers and duties, gives any *vested rights*, so to speak, which place it above or beyond the power of the creating body to review or regulate, is one not only without precedent in parliamentary law, but is untenable on any ground of parliamentary principle.'

"We have always been in accord with the sentiments expressed in Mr. Randall's opinion, and never imagined that Dr. Billings and his associates constituted an irresponsible committee; we only held that they were answerable to the Congress, and not to the national association, and that any instructions regarding the arrangements issued by the association were invalid, as the Congress has always made its arrangements through its own committee. But here we have a committee declaring itself to be irresponsible, a servant without a master. This combination calmly asserts that it is going to do the work, and that the Congress and profession generally will accept and approve of that work, whether they like it or not. Out in California we have had some experience of vigilance committees in troublous times, who were invested by the citizens with full powers to use all means to quell the disturbance, and this is the only irresponsible committee known in this State. Possibly this Executive Committee is of that nature, and has been appointed to carry out the purposes of Dr. King, of Missouri, who, when Dr. Billings's report was up for discussion at New Orleans, so eloquently advocated that 'the specialists of the new-code persuasion should be taken by the top of the head, and their throats cut at once.' We write in the greatest trepidation, lest from New York the wail of widows and orphans confirm our worst suspicions."

The "Medical Times and Gazette" says:

"Those of our English readers who have followed with painful interest the course of the struggle now in process in America with regard to the Washington Medical Congress of 1887 will be amused to hear that the new Executive Committee of the Congress have resolved that their actions '*are final, not being subject to revision, amendment, or alteration by either the Committee of Arrangements or the American Medical Association.*" The astuteness of that resolution is as remarkable as the irony of it is delicious. If the original committee had only been wise enough, before the event, to have adopted such a decision,

there would have been none of the dissensions which have so terribly distracted the American profession. The resolution is at once a slap in the face to the American Medical Association and a sneer at the original committee of eight, as if to say, 'Why, what idiots you were, not to have thought of this!' And yet it is at the same time a score to the original committee and its supporters in that it is a justification of their action in resenting the interference of the association with their decisions. Meanwhile we hear affairs are *in statu quo*. The resignation of Dr. Dalton, the chairman of the physiological section, which has happened since we last wrote on the subject, leaves the organization of the Congress without a single really scientific representative if we except the Flints and Dr. N. S. Davis. If the meeting is held, the sections of anatomy, physiology, and pathology will not be attended by any of the American workers in those fields. There is, we fear, little hope now of an arrangement. All the prominent American men of science have withdrawn, and will not return unless very considerable concessions are made, of which there appears no hope. The 'Berliner klinische Wochenschrift' this week roundly states that hardly a single 'medical personage' will be found to undertake the voyage from Germany for the privilege of sitting under the presidency of Dr. Shoemaker. It makes, however, a strong appeal to the American Medical Association to approach the subject in a more wise and generous spirit when its next spring assembly takes place, and to re-arrange its propositions in such a manner that the services of the leaders who were nominated in the first instance may still be made available. In the absence of such a re-arrangement, our Berlin contemporary expresses a decided opinion, which we can heartily indorse, that the Congress of 1887 will be foredoomed to dismal failure. The whole thing is a bad business. It is an awkward position, for it must be remembered that the Washington Congress will have to make arrangements for the succeeding meeting. Suppose Dr. Shoemaker and his friends decide that the Congress of 1890 shall be held in Texas!"

The Charity Organization Society.—Mr. Kellogg, the organizing secretary of the society, asks us to give notice that, in compliance with many requests from officers in charge of medical institutions, the society invites the medical staffs and the boards of managers of the several hospitals and dispensaries of New York to meet at the Hall of the Academy of Medicine on Friday evening, November 20th, at 8 o'clock, to confer together concerning the existing abuses and misapplication of medical charity, and to consider how these abuses may be remedied through the registration system and other facilities of the Charity Organization Society.

The Health of Michigan.—It appears by a summary for the four weeks ending October 31st, issued by Dr. Henry B. Baker, the secretary of the State Board of Health, that diphtheria was reported from fifty-nine places, scarlet fever from forty-one, typhoid fever from thirty-six, and measles from three.

THERAPEUTICAL NOTES.

The Treatment of Expulsive Gingivitis and Osteo-periostitis.—The frequency with which physicians practicing in small communities, where the services of a dentist are not always to be had, are called upon to treat recession of the gums, and the accompanying osteo-periostitis, has led a French journal styled "L'Odontalgie" (quoted in the "Gaz. hebdom. de méd. et de chir.") to summarize the treatment recommended by Dr. Mailhol, of the Argentine Republic. That gentleman employs treatment preparatory to medication with iodine, after having freed the teeth from tartar, especially by means of a collutory made after the following formula:

Boric acid in fine powder	75 grains;
Saturated chloroform-water	3 ounces.

Dissolve the boric acid, and add:

Distilled anise-water	3 ounces;
Distilled water	6 "

Shake and filter.

For the treatment of alveolo-dental osteo-periostitis, the author formerly used chromic acid, as advised by M. Magitot, but now he agrees with Dr. Harlan ("Dental Cosmos") in preferring iodide of zinc. The cavities are first washed out with the collutory, by means of a syringe, and then filled with cotton medicated with chloral, glycerin, and a solution of iodoform in its own weight of chloroform. The pain having been allayed, and the swelling having disappeared, the affected alveolar border is removed, and an injection is thrown into the cavity of a few drops of a solution of iodide of zinc in distilled water (1 to 40 at first, gradually increased in strength to 3 to 40).

An Ointment for Syphilitic Psoriasis.—The "Union médicale" attributes the following formula to Mauriac:

Oil of cade, Mercurial ointment, each	1 part;
Vaseline	15 parts.

To be used by inunction, morning and evening, for syphilitic psoriasis of the palms and soles.

The Treatment of Rheumatic Purulent Conjunctivitis.—In cases which show the clinical features and the gravity of gonorrhœal conjunctivitis, but in which the articular manifestations, the history, hereditary influence, and the absence of any urethral discharge have established the diagnosis, M. Perrin (*Ibid.*) advises, in addition to cauterizations with a fifty-per-cent. solution of nitrate of silver, the frequent use of a mixture of one part of alcohol to three parts of water, either as a lotion or in the form of spray. At the same time, antirheumatic medicines should be given internally, especially salicylate of sodium.

Huchard's Hæmostatic Pills.—The same journal gives the following formula:

Ergotin, Sulphate of quinine, each	30 grains;
Powdered digitalis, Extract of hyoscyamus, each	3 "

Divide into twenty pills. Five, eight, or ten are to be given daily, for various forms of hæmorrhage, such as metrorrhagia, epistaxis, and hæmoptysis.

Copaiba in the Treatment of Elytritis.—For various forms of inflammation of the vagina, whether due to a specific virus, to local irritation, or to a constitutional condition, M. Baratier ("Thèse de Paris"; "Bull. gén. de thérap.") recommends the following treatment, which he has often seen Professor Ball employ: Every second day a suppository made after the following formula is placed in the vagina, where it is allowed to remain for twelve hours:

Solidified copaiba, Cocoa butter, each	75 grains;
Extract of opium	¾ grain.

This mode of using copaiba is said not to produce unpleasant results. The cure is complete in about twenty days.

The Treatment of Contraction of the Palmar Fascia without Operation.—M. Costilhes ("Jour de méd. et de chir. prat."; "Lyon méd.") has collected many instances of the success of Vulpian's treatment, which consists in the prolonged use of this ointment:

Lard or vaseline	20 parts;
Iodide of potassium	10 "
Tincture of iodine	2 "

The ointment should be applied abundantly to the whole surface of the palm, and the hand should be covered with a thick layer of cotton, over which several turns of a bandage are applied. The dressing should be renewed every day until complete desquamation of the palm is produced. Sometimes the results are very rapid, great improvement being manifested at the end of a fortnight. Iodide of potassium may be given internally at the same time, and massage employed.

Lactic Acid in the Treatment of Laryngeal Tuberculosis.—In view of the general failure of other therapeutical measures, Dr. H. Krause (Berlin. klin. Wchnschr."; "Ctrlbl. f. klin. Med.") has taken a hint from von Mosetig-Moorhof's use of lactic acid for lupus, fungous caries, etc., and treated laryngeal phthisis with this agent, using solutions of from twenty-five to eighty per cent. He reports a decrease of the swelling and infiltration, the formation of healthy granulations on the ulcerated surfaces, the disappearance of the papillary excrescences, the contraction and gradual cicatrization of the ulcers, and an improvement in the subjective condition of the patients.

Original Communications.

MEMBRANOUS DYSMENORRHŒA.*

BY ALEXANDER J. C. SKENE, M. D., BROOKLYN,
PROFESSOR OF THE MEDICAL AND SURGICAL DISEASES OF WOMEN IN THE LONG ISLAND COLLEGE HOSPITAL.

MEMBRANOUS DYSMENORRHŒA is an affection which, although rather rare, commands very urgently the attention of the gynæcologist, because of the dreadful suffering which it gives rise to, and the obstinacy with which it has heretofore resisted treatment. There is a marked uniformity about this disease. In its pathology and clinical history it varies but little in different cases. A number of affections resemble this one to a limited extent, but it stands out well defined, and is easily detected by the experienced diagnostician.

Membranous dysmenorrhœa is an exfoliation in mass of the mucous membrane of the cavity of the body of the uterus at the menstrual period. Microscopically, the mass presents all the histological elements of the true mucous membrane of the uterus, including the utricular glands, unchanged by any new or abnormal elements. When it is expelled entire, it represents a complete cast of the cavity of the uterus, and is triangular, with an irregular opening at each of the angles, the one representing the internal os uteri, and the other corresponding to the ostia of the Fallopian tubes. This membrane is rather ragged on the outer surface, but smooth on the inner, and looks exactly as the lining membrane of the uterus does when in position. The size is usually about an inch long and less than that in width, and is generally somewhat larger than the normal proportions of the cavity of the uterus; but this is not always the case. In this respect it is apparently like the decidua of pregnancy; in fact, in general appearance it closely resembles the decidua vera, but there is a decided difference in its microscopic elements, sufficient at least to differentiate. This similarity of the two membranes has led to their being called the decidua gravida and the decidua menstrualis, the former being the mucous membrane as seen in abortion at a very early stage of gestation, the other the membrane as thrown off at menstruation in this morbid form.

Comparing the behavior of the mucous membrane in membranous dysmenorrhœa with its changes in normal menstruation, the difference is as follows: In normal menstruation, if we accept the views of Dr. Williams, of London, the whole mucous membrane undergoes fatty degeneration, disintegration, and elimination, whereas in membranous dysmenorrhœa the mucous membrane becomes separated from the walls of the uterus without being changed or disintegrated; exfoliation and expulsion simply occur. The way in which the separation of the mucous membrane takes place is not positively known. It is presumed, however, that fatty degeneration in the deeper structures of the membrane takes place, and thereby it becomes detached from the uterus. It is possible, also, that the capillary hæmorrhage, instead of occurring on the free surface of the membrane, takes place in the deeper structures, and in that way dissects off the membrane. This, however, is hypothetical, and needs confirmation. Sometimes the membrane is expelled in shreds, which suggests that the exfoliation either occurs in spots or sections, or else that the membrane is completely separated from the uterus, but becomes broken up either during expulsion or in handling it afterward. It is much more probable that it is completely exfoliated and broken up subsequently than that it is separated in circumscribed patches. All these facts lead to the conclusion that the affection is a perversion of nutrition and function rather than an organic disease, inflammatory or otherwise, which gives rise to this peculiar behavior of the mucous membrane at menstruation. It is clearly evident that there is nothing pathological in the condition of the mucous membrane itself, but that the whole morbid process consists in the separation of the membrane in mass, in place of disintegration, which is the normal behavior of the mucous membrane in menstruation. There are other views regarding the pathology of this affection: one, that it is the result of gestation, which is arrested at a very early stage, and the membrane thrown off is really a decidua vera. That this theory is fallacious will be seen when we come to discuss the physical signs of this affection.

The idea that it is an inflammatory affection can not be sustained. No such product or result of inflammation is found elsewhere in the mucous membrane of the body, nor is it necessary that inflammation of any part of the uterus should be present in order to produce membranous dysmenorrhœa.

Associated with this membranous dysmenorrhœa we occasionally find inflammatory conditions, but not of the mucous membrane of the cavity of the body. There may be, and often is, a general hyperæmia of the uterus and vagina, but usually it is not greater than that which is seen in normal menstruation.

There is occasionally, in cases of long standing, cervical endometritis, but this does not extend to the body of the uterus. In fact, I believe that a well-defined endometritis can not occur at the same time as membranous dysmenorrhœa. This affection, then, is certainly *sui generis*, and is not the result of inflammation in any form or any stage of the inflammatory process; neither is it a utero-gestation ending in abortion at a very early stage of pregnancy, as some have maintained; neither does the membrane partake of the nature of any of the morbid neoplasms which occur in mucous membranes elsewhere in the body.

The mucous membrane in this affection is developed in the natural way after each menstruation, and the gross appearances and histological composition of this structure show that it is normal, and differs in no way from the mucous membrane of the uterus up to the time when the menstrual flow is about to begin. Perhaps there is, in some cases, an increase in the quantity of the membrane, but only to a very limited extent, if at all. In short, the only pathological lesion in this affection is in the manner in which the membrane is thrown off.

* Read before the Medical Society of the County of Kings, September 15, 1885.

Symptoms.—This affection occurs in single and married women—about as often in one class as the other, perhaps. It also occurs in those who have borne children, but in most of the cases that I have seen in married women the patients have been sterile. The recurrence of the menstruation is generally regular; sometimes it is delayed, and sometimes there is a sense of pelvic discomfort before the menstrual flow, but not always. The chief symptom is the pain which comes on usually during the first day, sometimes later, and increases in severity and is somewhat intermittent in character until the membrane is expelled, when it rather abruptly subsides.

The flow sometimes is scanty previous to the expulsion of the membrane, and after that it is generally quite free; at times abnormally so, and occasionally small clots are passed.

Sometimes there is a leucorrhœal discharge succeeding the menstrual flow, the discharge being occasionally tinged with blood. In other cases the menstrual flow subsides after the expulsion of the membrane, and no leucorrhœa of any account occurs afterward.

There is really nothing in the clinical history of this affection by which it can be positively distinguished from dysmenorrhœa due to other causes. Hence the diagnosis must always depend upon the physical signs.

Physical Signs.—In order to make a diagnosis, it is absolutely necessary that the membrane expelled should be preserved and examined. The gross appearances of the specimen are usually all that is necessary to satisfy the diagnostician regarding the nature of the affection, but in cases where there is a doubt the microscope must be called in to aid in the diagnosis.

The morbid materials expelled from the uterus which simulate the membrane produced in this affection are the decidua expelled in abortion in the earliest stages of pregnancy; the masses of fibrin which have formed in the uterus in menorrhagia; very dense masses of secretion from the cervix; and the membranous-looking shreds expelled from the cervix and vagina after astringent or caustic applications.

The decidua in early abortion is most difficult to distinguish from the menstrual membrane. In the early abortion the membrane expelled is usually larger and more ovoid or round, and not so markedly triangular as the decidua of menstruation, and is also thicker, and usually is accompanied with villi of the chorion. If there is still a doubt, the microscope reveals that the menstrual membrane shows only small cells, while those of the decidua-vera membrane are so great as to be easily distinguished. There is a decided microscopic difference in the epithelium, the tubes, and the inter-glandular tissue. This difference between the two membranes is not only in the decidua of early abortion, but also in the decidua of extra-uterine pregnancy. In being thus able to distinguish between the decidua of pregnancy and the membrane of menstruation, the only great difficulty in the diagnosis is overcome.

The shreds of fibrin expelled from the uterus sometimes look membranous in form, but have none of the structure of the mucous membrane, and hence can be detected on cursory examination. The same may be said of the masses of unusually dense secretion of the cervix. The membranous shreds that come from the cervix and the vagina as the result of astringent and caustic applications resemble at first sight the menstrual membrane. The most perfect of these exfoliations from the vagina I have seen after the use of the persulphate of iron; these specimens, however, are much thinner and differ entirely in structure, being made up mostly of epithelium, and therefore need not be mistaken for the menstrual membrane.

With due attention to the membrane expelled, the diagnosis can be made with great certainty.

Causation.—Discarding the current views regarding membranous dysmenorrhœa—that is, that it is due to inflammation, or else the result of gestation—one is left without any very rational views to offer regarding the causation of this disease. While it is not, perhaps, the part of wisdom to discredit the accepted views on any question in medicine until one has something more reliable to offer, still, if the causes assigned can be readily shown to be incorrect, it is infinitely better and safer to be entirely in ignorance of the causes of things than to attribute them to the wrong causes. Fortunately, however, while I find myself at variance with most of the recent authorities regarding the cause of this affection, I am in perfect harmony with the views of Dr. Oldham, who was the first to discover dysmenorrhœa membranacea.

Dr. Oldham distinctly pointed out the characteristics of this affection and stated that the membrane was formed under the ovarian stimulus, and I am fully satisfied that he was not only the discoverer of the disease, but also conceived the true idea regarding the cause of it—viz., some undue or abnormal ovarian influence or sexual excitation. In other words, it would appear to be some derangement of innervation and nutrition.

Taking this view of the causation, I expect to find myself in harmony with the neurologists at least. This class of specialists manifest a willingness to trace many diseases originally to some derangement of the nervous system, when they find anything like good reasons for so doing. Hence, I expect their support in choosing, as I do, to believe that the starting-point in the pathology of this affection must be some derangement of innervation produced by disease of some associated organs like the ovaries. We might find confirmation of this view regarding the cause of membranous dysmenorrhœa in studying the agencies which give rise to other morbid states of the uterus, like the fibroid growth for example, which in its anatomical elements does not differ especially from the tissues of the uterus from which it springs; and, if we could find the cause of this deviation from healthy nutrition, it might be applicable to the disease under discussion. But, unfortunately, the causes of fibroid tumors given in our literature are unsatisfactory and by no means well sustained.

From the fact that uterine fibroids are more common in sterile women than in others, it would appear that sterility predisposes to their development, and perhaps no better explanation of the cause of these growths has ever been given than that of my somewhat humorous friend, who said that

"the uterus, being prepared for normal work and not finding it to do, took up the development of fibroids as a sort of outlet to its formative powers." May it not, then, be that a well-defined predisposition to reproduction, uncalled for by gestation, excites this morbid action on the part of the uterus which leads to this abnormal exfoliation of its mucous membrane? This view might at least be entertained, because in other cases, when we are unable to detect the cause of a disease in something that is tangible, we usually attribute it to deranged innervation and consequent malnutrition. This view of the causation is, to some extent, sustained by the effects of medicines upon the lesions. This affection has always been recognized as one that is often difficult to cure, many times incurable, in the hands of the most competent physicians and surgeons. This possibly may have been due to misapprehension of the nature and cause of the disease, and hence fallacious therapeutics, rather than to the incurable character of the disease.

In favor of this line of thought I may state that the patients whom I have treated in years past, on the theory that the cause was inflammatory, have derived little benefit, while those who were treated for deranged innervation, malnutrition, and undue ovarian excitation, have made very much better progress. I am inclined to attribute most of the trouble to ovarian influence, the condition of the ovaries being that of an undue nerve excitation and possible congestion. I have been led to this belief by two facts: that the majority of the patients that I have seen have been subjects of a highly nervous organization, and in most of them there has been tenderness of the ovaries, and pain at times in them, without there being any evidence of their having ovaritis.

The rheumatic diathesis is said to favor this affection, and it is possible that that may be so, although I am unable to recall any of my patients as being rheumatic; neither have I been able to trace this to the tubercular or strumous diathesis, nor to syphilis. It is certain, however, that, if either of those conditions existed, they would have their influence in helping to keep up the uterine trouble, and every effort should be made to relieve them by treatment.

Treatment.—The treatment of this affection is necessarily both palliative and curative. While the patient is suffering during the expulsion of the membrane, it is very necessary to relieve the pain as far as possible. This, of course, can be most promptly done by the use of opium, which should be avoided if possible, however, because of its after-effects.

Chloral hydrate answers fairly well in some cases. I was induced to try this agent by the accounts given of its effects in relieving the pains of the first stage of labor. I am not sure that it has any advantages over chloroform, camphor and belladonna, or conium and *Cannabis indica;* in fact, in the majority of cases, one has an opportunity to try several agents, and, of course, the patient will decide which gives most relief. Indications for general treatment are to quiet all nervous disturbance and to improve the general nutrition of the mucous membrane. It so happens that when the first part is attended to the latter will follow in due order.

To quiet the nervous irritation and disturbance there is nothing that equals the bromide of sodium. This should be given in twenty- or thirty-grain doses three times a day for ten days or two weeks before the menstrual period. And, if the pain is not severe enough to require the addition of some of the remedies already named to relieve pain, it may be continued throughout the menstrual period and several days after. From this it would appear that the bromide is to be used continuously; but one or two weeks in each month it can be omitted. When the bromide has been employed for some time, and it seems desirable to give it up, conium may be given in moderate doses combined with camphor, if the patient is weak. If there is any evidence of the rheumatic diathesis, the bromide of lithium should be given. Next to quieting the nervous system, any debility that may exist should be overcome by nerve tonics. Undue nervous excitation so often goes hand in hand with nervous depression that in many cases it is necessary to combine the tonic and sedative treatment. All the remedies which may be used need not be here mentioned. In regard to the modification of nutrition, it need only be said here that any accompanying derangements of the digestive organs that may be found should receive careful attention; but this hardly need be mentioned in this connection.

My rule of treatment has been, after subduing all nervous disturbances, to put the patient upon the iodide of sodium in case she is in fair strength and inclined to flesh. If there is anæmia, I prefer the iodide of iron. If these did not accomplish the object, I have employed mercury, giving it in small doses, never continued long enough to produce salivation, carefully watching to avoid this. In cases of anæmia, where I have feared the debilitating effect of this alterative, I have given the bichloride of mercury with iron. After keeping them upon this treatment until I could see some evidence of its effects, I have then put them upon iodine and arsenic.

In regard to local treatment, I have been entirely guided by the views of pathology expressed above, and have therefore employed alteratives and sedatives almost exclusively. Of these I have found iodoform most effectual. I have also used iodine and mercury with advantage. In cases where I have found any complications I have carefully attended to them, restoring displacements and correcting flexions, and so on. When the canal of the cervix has been at all constricted I have enlarged it by incision and dilatation.

When the congestion which occurs at the menstrual period does not subside in a few days, I have employed the warm-water douche. After this, I have applied to the cavity of the uterus small bougies of cocoa-butter with as much iodoform as it would take up. Three or four grains of iodoform mixed with vaseline that has been liquefied by heat, and introduced through the pipette, is perhaps the best method of applying it. These have been introduced once a week or once every five days. When there has been much tenderness, and the use of the pencils has caused pain, I formerly used aconite and opium and iodine; this I have introduced into the cavity of the uterus. I am now trying cocaine to subdue the tenderness as a preparatory

means to the use of the iodoform. But so far this new remedy has not been a perfect success.

In cases where this has failed and the uterus was not especially sensitive to intra-uterine medication, I have instilled into the uterine cavity a few drops of a five-per-cent. solution of carbolic acid, making one application a few days after the menstrual flow and not repeating it until the next period. In the interval I have used the iodoform. I have also used the fluid extract of conium and *Hydrastis canadensis;* but this I have found gives more pain than any of the other applications that I have used; and so of late I have used an infusion of the hydrastis alone, which appears to answer as well and gives less pain.

Case I.—*Membranous Dysmenorrhœa in a Married Lady who was never Pregnant.*—This patient was forty-one years of age, of good constitution, and had been married eight years. She began to menstruate at thirteen, and continued to do so regularly and normally until she was twenty-one; then she began to have occasional pain, about the menstrual period, in the region of the ovaries. About a year after this she began to have severe uterine pains during the menses, and states that she occasionally passed masses that looked like membrane from the uterus; they were small, however, and did not occur at each period.

After her marriage the pain at the menstrual periods became worse, and almost every month she passed a membranous cast of the uterus. The usual history of each menstruation is that the flow begins not very free, and, after continuing for about five hours, the pain becomes very intense and lasts from three to eight hours, when she expels the membrane and the pain subsides, the flow continuing for a day or a day and a half after the membrane has been expelled.

The flow, taken altogether, is not profuse, and only lasts from two to two and a half days, while formerly—that is, before her dysmenorrhœa began—it used to continue from four to five days. When first seen, her general health was good, but she was rather hysterical and nervous, and was somewhat depressed and disappointed because she had not had children.

She described her suffering at her menstrual periods as something unbearable, although it did not last more than a few hours at a time. She was first examined midway between the menstrual periods. The uterus was then found to be normal in size and in good position. The internal os was rather sensitive and appeared to be slightly contracted; there was also an extended Nabothian gland in the middle third of the cervical canal, but the uterus presented a normal appearance in every other respect. There was no congestion; in fact, at this time the mucous membrane appeared rather anæmic.

The diagnosis was left an open question until the next menstrual period, when I obtained the membrane expelled and had it examined by my friend, Professor Frank Ferguson. His report stated that the specimen was uterine mucous membrane unchanged in its histological composition. This settled the question of diagnosis.

Careful inquiry elicited the fact that she had never been pregnant, so far as I could rely upon her testimony, which I believe to be accurate because of her great desire to have children. I also learned that on several occasions she had lived apart from her husband, who was of necessity absent on business for several months at a time, and that she suffered just the same, and at each month there was an expulsion of membrane, showing conclusively that there was no possibility of mistaking this affection for pregnancy and abortion.

The treatment consisted, first, in placing her upon the following mixture: Half a grain of the bichloride of mercury, one drachm of the solution of the chloride of arsenic, three drachms of the tincture of iron in a three-ounce mixture of syrup and water. A teaspoonful of this was given, well diluted, after each meal. At the same time the internal os was incised superficially in three places, dividing equally the circumference of the canal, and the distended Nabothian follicle was punctured and evacuated.

A week after this a sound was introduced of full size, and there was less tenderness; the tincture of iodine was then applied from just within the internal os downward. At the next menstrual period she had less pain, but it lasted just as long, and she passed a membrane unchanged, except it did not appear so thick as formerly.

From this onward the local treatment consisted in passing a full sized sound just beyond the internal os right after the menstrual period, and again in two weeks, and in nearly every six days about two grains of iodoform mixed with vaseline was passed into the cavity of the uterus, well up toward the fundus. This local treatment was continued without interruption for three months, and the first prescription, after it had been taken for two weeks, was followed by the iodide of iron, a grain and a half three times a day.

After the second month, and at her third menstrual period from the time that treatment began, she had no pain and passed no membrane. At the next period she passed several shreds, but nothing like a complete cast of the uterus.

The constitutional treatment, that is, alternating between the first prescription of mercury and arsenic and the iodide of iron, giving the first one for two weeks, and then the other, was continued for two months longer. The application of the iodoform was continued for one month longer, once every week, and once after her menstruation, at the end of the fourth month of the treatment. Since that time she has had no further trouble; her menses are regular, lasting about three days and entirely without pain or any discharge of membrane.

That was her record at least one year after she gave up treatment, since which time I have not heard from her.

Case II.—*Membranous Dysmenorrhœa occurring after Treatment for Anteflexion and One Miscarriage.*—A lady of very high culture and over-refinement, of a well-marked nervous temperament, but otherwise of good constitution, came under my observation when twenty-eight years of age; she had then been married a year and a half. She menstruated first at fourteen years, and continued to do so regularly, but with pain from the very beginning. The pain usually began a day or so before the flow and gradually diminished after. Her suffering at each period gradually increased until her marriage, when it became more severe. This, and the fact that she remained sterile, induced her to seek advice. I found her suffering from anteflexion of the body of the uterus and cervical endometritis; there was also tenderness of the left ovary on pressure. She was treated for the flexion and completely recovered. The dysmenorrhœa was entirely relieved and she became pregnant. During her pregnancy she suffered very much from morning sickness, and at the end of the third month began to show some signs of septicæmia; she then miscarried, and the ovum was found to be macerated, and probably had been dead *in utero* for two weeks. She recovered from this and was quite well for about a year, when her dysmenorrhœa returned; she then returned to be treated for what she supposed to be a recurrence of her former trouble, but I found no evidence of the former flexion. But, on inquiry, I found that she passed at each period a membranous cast of the uterus. The patient thought little of this, because, in former years while suffering from the dysmenorrhœa caused by flexion, she occasionally passed small clots which looked some-

what membranous in character, but no doubt were simply blood-clots.

She was placed upon treatment similar to that employed in the first case reported, except that there was no necessity for enlarging the internal os as in the former case, the only difference in the local treatment being that I used iodine in place of iodoform during the last two months of the treatment; and once, immediately after her menstrual period, I applied a mild solution of carbolic acid to the uterine cavity.

She did not again pass any membrane after the third month of treatment, and her pain from menstruation entirely disappeared.

She was dismissed at the end of four months, and two months afterward reported that she was pregnant. Three months after that time she was examined and found to be so, and was progressing well. Since that time I have not seen her, but heard that she gave birth to a healthy child.

Case III.—*Membranous Dysmenorrhœa treated by Dr. Fordyce Barker, of New York; Complete Recovery.*—I give the history of the following case for two reasons: First, to show that iodoform was employed in the local treatment, and that the patient's recovery was complete; and also to take the opportunity of stating that I believe that Dr. Barker was the first to employ this agent.

The history is not altogether complete, because I obtained it from the patient herself, who was unable to tell all that was done for her; but I know positively that she suffered from dysmenorrhœa, and that she entirely recovered under the care of Dr. Barker, and has remained well for a number of years.

This was an educated lady of a well-marked nervous temperament; she began to menstruate at thirteen, and continued to do so normally until she was twenty-six years of age. At that time she was said to have had an acute attack of ovaritis, and after recovering from that she had dysmenorrhœa.

The character of the pain at her menstrual periods then appeared to be ovarian. After suffering in this manner for about four or five years she noticed the expulsion of membranous casts of the uterus at the menstrual periods. During this time and for a year afterward she was regularly treated by her family physician, but without relief. She then consulted Dr. Barker for her general ill-health, but did not call his attention to her derangement of the menstrual function. She improved in her general condition under his care, but found no relief from the membranous menstruation. She consulted him again and called his attention to the uterine trouble, and he immediately placed her under treatment.

The constitutional remedies employed I do not know, but the local treatment consisted in dilatation of the cervical canal and the application of iodoform to the uterine cavity.

She continued to pass membrane for several months; then the trouble ceased and has not returned. She now menstruates regularly and naturally, and has done so for over two years.

Several other cases might be added, some showing failure of treatment, and others where the patients were really made worse by being treated for inflammation of the uterus which was supposed to be the cause of the trouble, but undoubtedly was not. Other cases might be given, also, in which recovery took place, and after several months or years the trouble returned, but they would add nothing to the views already given regarding the pathology and treatment of this affection.

The Charcow Ophthalmological Clinic, according to the "St. Petersburger medicinische Wochenschrift," has lately received a legacy of 12,000 roubles, the interest of which is to be applied to the maintenance of additional free beds.

NOTES ON HOSPITAL OBSTETRICS.*

By CHARLES JEWETT, A. M., M. D., Brooklyn,
PROFESSOR OF OBSTETRICS IN THE LONG ISLAND COLLEGE HOSPITAL.

One hundred consecutive confinements at the Long Island College Hospital furnish the material for the greater part of these rambling observations. Seven cases of abortion, however, scattered through the same period, are of some interest, and, before entering upon the study of the term labors, I will state in brief detail the treatment pursued in abortions. All fell in the second or third month. All were treated by immediate removal of the secundines. Of the seven patients, three had high temperatures on admission, with putrid secundines. Another was extremely anæmic from hæmorrhage, and her condition was further complicated with delirium tremens. In all the uterus was immediately evacuated substantially as follows:

The patient was placed in the latero-prone position and the cervix exposed by means of Sims's speculum, and steadied with a volsella. First the vagina and then the uterus were thoroughly cleansed with a douche of the bichloride solution, 1 to 1,000. The secundines, if separated, were then removed with a uterine dressing forceps, and the cavity was curetted with the small dull curette. If the ovum was still partially adherent, it was first detached with the curette. The cavity of the uterus was finally irrigated a second time with bichloride solution and a soft iodoform pencil deposited therein. In the febrile cases the temperature promptly declined, and all pursued a favorable course, the patients being discharged in from five to ten days.

Sims's speculum has few more important uses than in the treatment of abortion. The detached ovum is extracted by the above-described method with almost as much ease as it could be picked up from the floor. The facility of removal is in striking contrast with the painful and awkward digital method of extraction.

The immediate evacuation of the uterus is demanded in the event of sepsis or much hæmorrhage. Even in the absence of these conditions I have generally preferred the immediate operation, including separation with the curette, when the ovum had clearly become a foreign body. I have seen no evil results from this course, while delay may expose the patient to a sepsis which later evacuation is powerless to arrest, to say nothing of the evils of hæmorrhage. The ordinary small dull curette answers the purpose, and has the advantage that but little dilatation is required. I have rarely used any other. The important point, when interference is practiced, is to operate if possible while the tissues of the ovum are still fresh, and to leave the uterus completely empty and aseptic. The radical treatment of abortion and the use of the Sims speculum were advocated several years ago by Dr. Skene.

The one hundred term-confinements were conducted in surroundings involving more or less septic exposure. The obstetric wards were in the oldest portion of the building and in immediate proximity with the surgical wards of the hospital. The obstetric interne was also on general medi-

* Read before the Medical Society of the County of Kings, September 15, 1885.

cal duty, and a certain number of students and nurses were admitted to witness the labors. Despite the unfavorable circumstances, no epidemic of fever prevailed. No two consecutive confinements were followed with serious fever, and the total number of cases that could be classed as uncomplicated puerperal septicæmia were only seven. In this number there were three deaths.

In several cases circumstances pointed clearly to the belief that the poison was conveyed by the attendants on the labor, and not by the atmosphere. Atmospheric infection, I am disposed to think, is the exception and not the rule. In the majority of cases puerperal sepsis must be attributed to the physician or nurse in attendance during the labor. Cleanly surroundings, however, are of course indispensable to the cleanly conduct of the labor.

Our antiseptic practices of the last year have been somewhat simplified. They consist mainly of measures addressed to the scrupulous cleanliness of everything that is brought in contact or proximity with the passages, particularly during labor. Antiseptics are often indispensable to this end, especially to the aseptic cleanliness of hands and instruments. Vaginal injections are not used in puerperal patients for prophylactic purposes, except when specially indicated. The usual lochial guard, however, is kept wet with the biehloride solution for the purpose of promoting an aseptic condition of the external genitals.

The lying-in department has within a few weeks been transferred to new quarters in the wing recently erected. It is wholly cut off from direct communication with other portions of the hospital buildings. It is accessible therefrom only through the open air. The wards are ranged on either side of a central corridor, and are provided with ample ventilation. In the convalescent wards and waiting-room pure air is admitted by a double system of flues, one for heated and one for cold air. The foul air is removed by flues communicating with a central upcast shaft, in which a strong draft is maintained the year round by means of a steam stack. Transom-windows add still further to the ventilating appliances, and all the incoming currents are regulated with reference to proper distribution so as to break up the entire volume of air in the room. A room for the isolation of fever patients is located in a remote portion of the wing.

All the wards have been constructed with a view to make them proof against the accumulation of hospital miasm. The walls and ceilings are finished with Keen's cement, and the floors are of concrete, painted. The woodwork is of the plainest kind, and the grain well filled. Since the walls and floors are like stone, in addition to the usual means of disinfection the wards may be flushed with a hose. A steam cylinder, which can be charged from the engine-boiler, is provided for disinfecting the bedding by high temperature.

Passing now to the analysis of the term confinements, the nationalities of the mothers were chiefly Irish, Swedish, and Americans of foreign extraction. The number of single women was forty. Fifty-six women were confined for the first time, forty-four were multiparæ. The youngest mother was seventeen years old. Of aged primiparæ there were six of ages ranging from twenty-nine to thirty-eight. All were delivered without artificial interference, and the average duration of their labors was a little below the average in the younger primiparæ. These cases prove only that dystocia does not always befall this class of parturients.

An unusually large proportion of maternal abnormities was encountered. There was one case of simple flattened pelvis, one of funnel-shaped or male pelvis, one kyphotic pelvis, and two cases of cancer of the cervix.

As there was one twin birth, one hundred and one children were born. Of this number, ninety-three presented by the vertex. There were four breech cases, two cross births, one head and hand, one head, hand, and funis presentation.

The proportion of vertex presentations conforms nearly to the usual average, which is generally stated at about ninety-six per cent. Only fourteen per cent. of the vertex cases are recorded as occipito-posterior positions. Since nearly one half of the patients, however, were more or less advanced in labor on admission, the records of position are inexact.

Seventy-seven labors were accomplished solely by the natural powers. There were thirteen forceps deliveries, three manual extractions in breech births, three cases of podalic version, one delivery with the blunt hook (a breech case, the child dead), one by craniotomy (child dead, deformed pelvis), one Cæsarean section, one laparo-elytrotomy. (The laparotomies will be found elsewhere reported.) The average weight of the children in the forceps cases was nearly eight pounds. Thus the child was an element in the dystocia.

In forceps operations the aim has been to deliver with a minimum amount of force. Probably in none of the above-mentioned cases did the traction force exceed fifty pounds. To deliver with the least possible force, three things are necessary:

1. Time. It is often possible to coax the head along very slowly with moderate traction when a rapid delivery would involve a great expenditure of strength and much violence to the mother. It is a law of mechanics that the resistance which a moving body meets with increases as the square of the velocity. This law is not wholly inapplicable in the forceps operation.

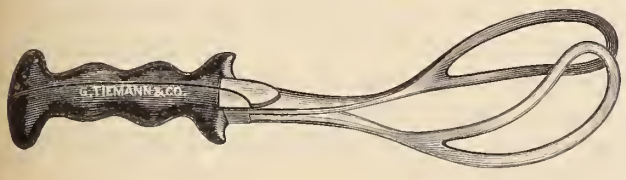
2. The previous correction, when possible, of malpositions of the head. This is not always possible.

3. Axis traction—in other words, the application of the force in the axis of the passages. Misdirection not only wastes force, but, worse than this, the waste force is expended in doing harm. The axis-traction forceps of Tarnier and its modifications offer great advantage in many cases of high operation. In these instruments the extracting force is applied in the axis of the forceps blades, and the axis of the blades lies constantly parallel with the axis of the passages as the head descends. The ordinary forceps should do the same thing. This can not be accomplished by mere traction upon the handles, certainly not with forceps having a marked pelvic curve. It may be done by conjoining with traction, applied at the handles by

one hand, a downward pressure with the other hand upon the shanks near the lock.

The operator is often in doubt as to the precise direction of the pelvic axis. I am not sure to whom I am indebted for the following useful hints for solving this difficulty and guiding the line of traction. The symphysis pubis is substantially parallel with the axis of the brim. The direction of the symphysis may be readily determined by laying the finger along its internal surface or by placing the finger-tips externally over the extremities of the symphysis. This affords a guide to the line of traction, which deviates but little from the axis of the inlet till the occipital pole approaches the pelvic floor. As the head glides along on the floor of the pelvis the forceps handles should sweep forward rapidly enough to make the anterior margins of the blades hug the ischio-pubic rami as closely as possible without crushing the intervening soft parts. These rules serve for general guidance in the use of forceps, but may of course require modification in individual cases.

In connection with this subject I submit a forceps which has been made for me by the Messrs. Tiemann & Co. It is designed to meet the requirements of modern obstetrics in the matter of cleanliness. The only important new feature is the construction of the handles. The handles are of hard rubber, smoothly polished, and they wholly envelop the metal. As the rubber is vulcanized upon the metal, there are no crevices for the lodgment of filth. With the exception of the handles, the general model of the instrument is similar to the Elliot forceps, but the shanks are stronger and the lock is a half Smellie.



In the seven breech extractions none of the children were lost except one, which was dead for two or three days before the admission of the mother. The method followed in breech deliveries is as follows: A forceps is always within reach of the hand. An assistant stands ready to apply pressure over the fundus at the critical moment—the delivery of the head. Anæsthetics are generally withheld to secure the full use of the expelling forces of the mother. In order to the full dilatation of the passages preparatory to the delivery of the after-coming head, the pelvic extremity of the fœtal ovoid is left intact—in other words, the extremities are, if practicable, allowed to remain flexed upon the abdomen, and the descent of the breech is not usually hastened by traction. Another reason for avoiding traction is the fact that the head and arms are liable to become extended if the trunk is dragged down. When traction becomes necessary in case of delayed or impacted breech, the attempt is made to maintain the flexion of the head by means of external pressure applied over the abdomen by the assistant. In the expulsion of the trunk much depends on the prompt delivery of the arms. If manual extraction of the after-coming head is not readily accomplished with moderate force, the trunk of the child is carried up over the abdomen of the mother and the forceps applied to the head. Great reliance is placed on the forceps in difficult delivery of the after-coming head. The application is easy, and, once applied, failure is practically impossible where a living child is possible by any method of extraction. On the other hand, manual methods in difficult cases frequently fail, and, when successful, are liable to inflict fatal injury upon the spinal cord.

Episiotomy was done in one case. In rare instances this procedure is believed to be good practice in rigid perinæum where extensive rupture of the perineal muscles would otherwise be inevitable. At the moment when the equator of the head is about to escape from the vagina, a narrow-bladed, blunt-pointed knife is laid flatwise between the head and the cord-like constricting ring just within the vaginal outlet. The incisions are made an inch or more from the median line, and should not much exceed half an inch in length and an eighth to a quarter of an inch in depth. I prefer to make the incisions during a pain, since they can be more readily managed while the ring is tense.

The compress and T-bandage suggested by Dr. Skene for support of the pelvic floor after labor, in certain perineal injuries, will be found useful after episiotomy. It should be understood that this operation is not advisable except where other measures are inadequate.

With the use of Credé's method the placenta was in the majority of cases expelled in from fifteen to twenty minutes after the birth of the child. The longest placental stage recorded was forty-five minutes. In delayed third stage, injection of the placenta through the cord has been found a useful measure, though by no means invariably successful. This practice is not new, having been advocated by various writers since the early part of the present century. I use a small hard-rubber cannula attached to the syringe, though a common quill toothpick will answer the purpose. Cold water is injected through the umbilical vein, care being used to avoid injection of air. The effect of the cold water, when successful, is to provoke a vigorous contraction, usually attended with prompt expulsion of the placenta. Manual extraction in retained placenta is avoided if possible, though little danger is to be apprehended if the hand is aseptic.

Lacerations at the vaginal orifice of some grade occurred in thirty-six cases. This number includes wounds of every degree beyond mere nicking of the hymeneal orifice or of the fourchette that could be detected on critical examination. All but three occurred in first labors. Eleven of this number were not of sufficient extent to involve the muscular structures of the perinæum; none extended through the sphincter ani. The proportion of perineal injuries may seem large, yet I am disposed to think it is little larger than would be found in general practice were the same opportunity afforded for careful examination. The number was no doubt increased by the fact that in a certain proportion of emergency cases brought on the ambulance the head was rapidly expelled before aid could be rendered. The methods practiced for the protection of the perinæum are chiefly preliminary dilatation, delay, and delivery of the head by its smallest circumference.

All except the most superficial rents were immediately closed with sutures. The single suture of Alloway was tried in two or three cases, but was unsatisfactory and was abandoned. No method can meet the indications which does not hold the sundered muscular structures in apposition throughout.

One perineal laceration extending into the sphincter ani united without sutures, forming a thick and firm muscular body. This patient was delivered fourteen hours before admission. On examination after she entered the hospital, the torn surfaces of the perinæum were found cemented together, and therefore no sutures were applied. The case is of interest because very exceptional, and is not referred to as affording a guide for the management of perineal ruptures.

Of fifteen multiparæ submitted to critical examination before labor, old perineal injuries sufficient to impair the function of the pelvic floor in some degree were found in nine. In four the damage to the muscular structures was out of proportion to the apparent injury, the mucous membrane and skin having remained nearly or quite intact, while the muscles had been more or less extensively sundered.

In twenty-eight primiparæ in whom the condition of the cervix at the date of discharge was recorded, lacerations were found in eighteen. All but seven of this number were of slight extent. These examinations, however, were made about ten days after labor, and probably all but the deepest fissures became insignificant by the time involution was complete.

In the one hundred mothers there were six deaths. One woman died of peritonitis and exhaustion three or four hours after delivery. She had been brought in after four days' labor with epithelioma of the cervix and a laceration opening into Douglas's pouch. The child was dead, and the breech, which presented, was fixed in the grip of the unyielding cervix. Another patient with cancer of the cervix died of peritonitis after Cæsarean section. This case has been elsewhere reported.

One death occurred from prolonged labor with deformed pelvis. This woman was admitted in a state of collapse, with a pulse of 180, after being about four days in labor, the head arrested at the pelvic outlet. The child was dead and putrid. Delivery was accomplished by craniotomy. The thorax and abdomen required to be punctured before the trunk could be delivered, owing to distension from putrefactive gases. The right vaginal wall was the seat of an extensive slough from long-continued pressure of the fœtal head. The woman died soon after delivery. The remaining three deaths were due to puerperal fever.

In fifty-six patients the temperature did not reach 100° during the post-partum week. There were four with moderate septic fever who recovered. The recoveries were due in large measure to antiseptic irrigation of the passages, a sharp decline of the temperature invariably following the douche, while in the three fatal cases of fever the douche made no impression on the temperature.

The remaining abnormal temperatures were due in some cases to pre-existing disease, as rheumatism, phthisis, etc.; in others to malarial poisoning, to mastitis; in several instances to emotional disturbance, and doubtless in a number of cases to slight transient absorption of decomposing lochia.

A case of labor in a diabetic subject is worthy of special mention. The woman was single and pregnant for the first time. She was delivered by the high forceps operation after twenty-six hours of ineffectual labor, the child weighing eight pounds and eight ounces. Chloroform was badly borne. She went into partial collapse after delivery, and was rallied with difficulty.

This patient had more or less fever for two weeks after labor, the temperature several times mounting to 103°. A partial laceration of the perinæum, which had been closed with sutures, failed of union, sloughs occurring on both sides of the rent. She had phlebitis of the superficial veins of the lower extremities. The seat of the punctures on the thigh, where fluid extract of ergot and dilute ammonia-water had been injected hypodermically, formed phlegmons, in two or three of which sloughs separated, exposing the muscular structures.

Dr. Dickinson, suspecting diabetes from the appearance of the wounds, confirmed the diagnosis on examining the urine for sugar. This case affords a good example of the dangers to which a diabetic woman is exposed in parturition. Sugar occurs physiologically in the urine of most women during the latter weeks of pregnancy and during lactation. Blot found it in half the cases examined during pregnancy. Dr. Angus Macdonald ("Ed. Med. Journal," August, 1881) examined the urine for sugar in thirty-four puerperal women and found from one to eight per cent. in all. This physiological glycosuria is intimately associated with lactation.

De Sinéty showed that the amount of sugar in the urine of puerperal women could be increased at will by abruptly suppressing the flow of milk. Barnes says the sugar disappears from the urine when the production and yield of milk are evenly balanced.

Diabetes as a complication of pregnancy and labor is rarely mentioned in the text-books. Dr. Matthews Duncan ("Obs. Trans.," London, 1882, p. 256), in a paper cited by Playfair, relates several cases. A large proportion of the children die before birth. Hydramnios is more frequent than in other gravidæ. But the principal dangers to this class of parturients are those of collapse after labor and their inability to bear well the traumatism of parturition.

Of the children, all but one were single births. Of the one hundred and one children, forty-five were females and fifty-six males. The relation of the fœtal pulse-rate to the sex was by no means constant, but in a large proportion of cases where the fœtal pulse before birth was much above 140, the child was a girl or a feeble male; where much below 140, the sex was generally male.

Ninety-four children were believed to be strictly full-time births. Of these, the average weight was seven pounds and one third, excluding the twins. The largest child weighed eleven pounds. The average length of the full-time children was a fraction less than nineteen inches. The length of the new-born child affords a convenient means for estimating the stage of development. The measurement may be roughly determined, even *in utero*, as a ready meth-

od of estimating the stage of gestation. The length of the fœtal ovoid can generally be readily measured. Double this measurement gives very nearly the total length of the fœtus.

A limited number of observations were made upon the temperature of the new-born child. The average rectal temperature in twenty infants at birth was 96·4°. On the second day the average was 98·5°, on the third 98·7°. The lowest temperatures occurred in puny and in partially asphyxiated children. The lowest noted at birth was 94°.

Four children were still-born, all dead before the admission of the mothers. One died from prolonged labor obstructed by cancer of the cervix, one from prolapsus funis, one from ante-partum hæmorrhage, and one child was dead and putrid from prolonged labor with narrow pelvis.

But one fœtal abnormity occurred. This was a case of atresia ani. The obstruction was a membranous septum which was punctured and the opening dilated by tearing. Subsequent dilatation was maintained by the mother's finger used as a bougie. The child was thriving when it left the hospital. A small glass speculum was found of great service in determining the extent of the occlusion and in puncturing the membrane without injury to surrounding structures. The speculum was improvised by cutting off an inch from the open end of a test-tube and rounding the cut edges in the flame of a spirit lamp.

A modified Credé's treatment has been for some time in use for the prevention of ophthalmia of the new-born infant. A few drops of a five-grain solution of nitrate of silver are instilled into the eyes of every child immediately after birth. No cases of ophthalmia have occurred since the adoption of this practice, while they were not wanting before.

In conclusion, my acknowledgments are due the house staff for intelligent and untiring interest in the clinic, and to Dr. R. L. Dickinson, clinical assistant to the chair of obstetrics, for valuable aid in securing accurate observations and for rare skill and judgment in directing the service.

THE GENERAL PATHOLOGY OF FEVER.*

By JOSEPH MERZBACH, M. D., Brooklyn,
gynæcologist to the southern hospital and dispensary.

Before entering upon the subject of my paper I may be allowed to make a few remarks on the physiological aspect and those modifications of temperature which we are accustomed to consider as normal.

Heat is the result of molecular motion, and temperature the expression of the velocity of this motion. The three factors on which the action of the relatively constant temperature of the human body is dependent are: the production of heat, the loss of heat, and the regulation of heat. Lavoisier was the first to pronounce the production of heat a process of oxidation—viz., a combination of oxygen in the air with the carbonic acid of the blood. All the later researches in this direction go to show that the greater part of the heat produced in the human body is brought about by this process, and that this process takes place in the tissues themselves and not in the lungs, as was believed by older physiologists. But where the amount of heat comes from not accounted for by oxidation has as yet not been determined.

This production of heat is counterbalanced by the constant loss of heat. Heat is lost by the introduction of air and food of a lower temperature than that of the body, by the evaporation of water from the surface of the lungs and skin, and by conduction and radiation of heat from the skin, as long as the temperature of the skin is higher than that of the surrounding atmosphere. Of these three agents, the skin is by far the most important, giving off eighty per cent. of the whole amount of heat produced in twenty-four hours; the lungs dispose of about eighteen per cent., while the remaining two per cent. is required for the heating of food.

This paramount position of the skin among the heat-losing organs, and its relation to the temperature of the surrounding atmosphere, ought not be lost sight of in the treatment of febrile disorders. I am very much inclined to ascribe the favorable results of out-door treatment in fevers more to the lower temperature and greater motion of the air, by which the skin is enabled to give off steadily quite a considerable amount of heat, than to the better quality of the atmosphere, although, as a matter of course, I am not prepared to deny the beneficial effect of the latter agent.

After having thus briefly touched upon the subject of production of heat and loss of heat, the question naturally arises: What is the arrangement by which the organism is enabled, even under very considerable variations of the surrounding temperature, to almost constantly maintain its own heat? There are several contrivances by which this object is accomplished, the most evident of which is probably the skin and the regulation taking place by the elasticity of the cutaneous capillaries. If the surrounding atmosphere is cold, the vessels contract, the difference between the temperature of the skin and atmosphere is lessened, and, consequently, the loss of heat is diminished. When the skin comes in contact with warm air, the cutaneous capillaries expand, the difference between the surrounding and internal temperature increases, and the loss of heat becomes greater. It must also be taken into consideration that in the first case the amount of blood exposed to the cooling influence of the air, and the action of the perspiratory glands, is less, while in the latter case it is greater, the supposition being in both cases that the temperature of the atmosphere is below that of the body.

By change of clothing the human being contributes toward regulation from the skin.

Another agent of regulation is the spontaneous increase or decrease of heat-production by change of food; the influence of this agent can not be proved for short spaces of time. In regard to longer periods, we find, as a matter of fact, that the inhabitants of colder climates not only take a larger amount of food than those of warmer regions, but also that they favor such articles of food as are likely to produce more heat. That the respiratory activity varies in

* Read before the Brooklyn Pathological Society, September 24, 1885.

different temperatures is generally conceded, while the share of the nervous system in the regulation of heat is still subject to much discussion. It is a matter of course that the nervous system, by its influence on the blood-vessels, must contribute toward regulating heat; but whether it has a more direct action is the question. The direct action undoubtedly takes place in muscles and glands; in these heat is generated on exciting their nerves, even after circulation in them is entirely stopped. But for all the other tissues of the body the influence of the nervous system could not be proved.

The existence of special caloric centers has not been experimentally demonstrated. All the experiments necessary for the removal of the nerve-centers so deeply affect the organism that the resulting changes in temperature may just as well be ascribed to the influence of the operation as to the absence of the nerve-centers. And yet there are clinical facts which, without the admission of such caloric centers, are difficult, if not impossible, of explanation. I have at present a man under observation who, four months ago, had an apoplectic stroke. The most annoying symptoms which remained therefrom till now are the following: A defect of vision on one side, slightly diminished memory, and cold feet. The symptom last mentioned can not be explained by a lesser degree of mental or muscular activity, because the man is just as energetic and active as before. It also can not be traced to a lesser amount of food, because his nourishment is of the same quantity and quality as formerly. It therefore seems rational to suppose, in this case at least, that the cerebral injury has involved special caloric centers.

After thus having called your attention to the three factors essential to the maintenance of the relatively constant temperature of the human body, let me briefly review some of the conditions which normally modify its constancy. Age produces variations in this way: that the temperature, which immediately after birth is 99·5° to 100°, falls after the first bath to 98·6°, to rise again to about 99°. It then gradually falls one per cent. up to the age of fifty. Between fifty and sixty it remains constant, to rise again, so that at the age of eighty the temperature equals that of the new-born.

Sex has no perceptible influence.

The diurnal deviations are from 97·2°, at 5 to 6 o'clock, to 98·9° between 5 and 7 o'clock P. M.

The influence of food is not considerable enough to attract our special attention. It may be said, though, that the fall of temperature as the result of cold drinks is somewhat more considerable than the rise produced by hot ingesta. Alcohol, even in moderate doses, reduces temperature, probably as the result of a greater loss of heat through changed circulation.

Muscular exercise may cause a rise of from ·5° to nearly 2°. The abnormally high temperature of tetanus is certainly not due alone to muscular work, but also to the underlying pathological condition, and possibly to a narrowing of the capillaries, by which the loss of heat is diminished.

Mental work influences temperature but slightly, at least in our climate; in tropical countries a rise of 2° has been observed. In modification of this statement I must remark that the president of this society, Dr. B. F. Westbrook, succeeded, by great mental concentration, in producing a rise of 2°; I myself was not able to increase my temperature by mental work more than 0·4°.

The surrounding atmosphere has no remarkable influence as long as the mode of living, food, and clothing are appropriate; these being defective, very low temperatures may produce a fall of heat sufficient to cause death. Very high temperatures can be borne to a remarkable degree in a dry atmosphere. The danger of sunstroke is greater, of course, in a saturated atmosphere and with muscular exertion.

Normal menstruation and pregnancy do not influence the bodily heat; the higher temperature of the pregnant uterus is partly due to the fœtal production of heat, partly to the great muscular development of the organ. After delivery, the temperature rises almost invariably, and we all know how difficult it is to fix a boundary between normal and abnormal; and it will always be necessary for the formation of a correct judgment not to rely upon the thermometer alone, but to take all the concomitant circumstances into consideration. The influence of refrigeration on the temperature of the body, in the present state of therapeutics in fever, requires mentioning. The first effect of cold applications—and an effect more marked in proportion to the extent and intensity of the application—is a slight rise of the axillary with a fall of peripheral and rectal temperature, while the continuance will change the axillary increase into a decrease, and will force still lower down the peripheral and rectal temperature. The difference of behavior between the axillary temperature and that of other regions has been explained by Liebermeister through a relation between heat-production and loss of heat. He holds, and seemingly proved by calorimetric researches, that the production of heat increases in proportion to the loss, and that, as long as the loss of heat does not take on an extent which can not be antagonized by increased heat-production, the internal temperature will be higher in proportion to the lowering of peripheral heat. This explanation was based on experiments which with other observers did not by any means yield identical results; and besides that it does not agree with the fact that the temperature in the rectum, and even in the vena cava inferior (Ackermann), declines at once as the result of refrigeration. The axillary rise has so far not found a satisfactory explanation; the most plausible theory is that the only vaso-motor nerves not subject to the irritating influence of refrigeration are those governing the muscular blood-supply, and that these, instead of producing contraction, allow their blood-vessels to expand under the increased blood-pressure; therefore the temperature of the muscular tissues which is found in the axilla rises, while the peripheral and internal temperatures decline. Whichever theory may be right, there is a general agreement about the clinical fact (and this is of paramount importance to us) that the general temperature of the body declines after a more or less continued application of external cold.

Great reduction of temperature is also brought about by considerable losses of blood and the injection of gases

into the abdominal cavity. I need not go into the *modus operandi* thereof, as the subject of my paper gives me more interest in the exploration of the causes which produce high temperature. Elevation of temperature is the only symptom which is common to all fevers, and we may therefore define fever as a general disturbance of the system, the pathognomonic sign of which is an increased temperature. Hence the Latin "febris," from "ferveo," I am warm, and the Greek "pyrexia," from πῦρ, πυρός, the fire. All the other symptoms—as dryness of the skin, increased action of the heart, change of secretions, chills, nausea, and thirst—may be absent. On the other hand, headache, pains in the back, and a feeling of fatigue, which we so commonly find in fevers, may be present in other conditions of the system which lack an elevation of temperature. Therefore I think we are justified in designating the elevation of temperature as the only sign by which we are always enabled to make the diagnosis of fever.

The pathogeny of fever has always eminently occupied the minds of medical men, as may be expected from the importance of its position among diseases; and the history of theories on fevers, like that of other diseases, teaches "the imperfection of one pathological view for the explanation of all the symptoms of a given disturbance. According to the prevailing theory of the times, fever has been explained by physical and by chemical processes—by changes in the vascular system, by derangement of the nervous system, by increase or decrease of tissue-irritability," etc.

Even philosophy and religion have been made use of for the explanation of the morbid phenomena of fever; thus I may mention, for the sake of curiosity, that Stahl, according to whom all vital processes were controlled by a single principle—the soul—defined fever as "an almost conscious motor, secretory, and excretory act for the removal of noxious matters." To discuss all the theories mentioned, to give all the arguments in favor of and against every one of them, would lead me too far. I may therefore be allowed to proceed at once to the modern views on the pathology of fever.

That there is at the root of every fever something foreign to the normal blood is generally accepted; it may come from without, as in infectious diseases, or it may be formed within the organism, as in septic processes. About the nature and character of the disturbing element there are just at present numerous theories. Bacilli, fungi, bacteria, and micrococci are discovered one day, to be mercilessly murdered the next. We may safely say that, with very few exceptions, the microscope thus far has failed to demonstrate the entity and the differential character of the modern microphytes so as to insure their general acknowledgment. We are therefore compelled to leave this question, and we now ask in what way does the disturbing element affect the system?

Is the blood but the carrier of these little organisms, which, upon their arrival in the tissues, modify metamorphosis? Or does the presence of these elements cause an intermediate product in the blood which irritates the tissues? Furthermore, does the disturbing element act on the tissues directly or by the intervention of the nervous system? And, if the nervous system is responsible, is the central nervous system directly irritated by the foreign element carried to it by the blood? Or has the disturbance primarily acted on peripheral nerves, whence the irritation is communicated to the central nervous system?

All the attempts to answer these questions have so far been resultless, and all the theories which take for their foundation either blood, or tissues, or peripheral nerves, or the central nervous system, have been refuted, notwithstanding the able advocates they found. It seems highly probable, therefore, that all these organs have their share in the primary causation of fever, and that the greater or lesser extent to which their share in a special case is limited depends on the nature and character of the disturbing element. In other words, I do believe that every attempt at the pathological generalization of fevers will be futile, and that, for the explanation of all the symptoms of a given case, it will be necessary to determine more accurately the special and differential character of the disturbing cause.

For an explanation of the most prominent phenomena we must go back to our three great factors in animal heat—viz., heat-production, loss of heat, and regulation of heat.

That heat-production is increased in fever may be admitted as generally conceded; also that the process of combustion extends more to nitrogenous than non-nitrogenous substances. Of course, this factor alone can not be held responsible for the causation of an increased temperature, because then we should have elevation of temperature in all conditions of the system where combustion is increased—for instance, after meals. That this is not the case was shown in my remarks on the normal modifications of heat. Traube's theory, by which he explained the phenomena of fever by diminished loss of heat, is opposed by the following considerations: It has not been proved that the contraction of the small arteries precedes the other phenomena of fever; it can not, therefore, be asserted that this contraction maintains a causal relation to the rise of temperature. Secondly, were the pyrexia due only to the diminished loss of heat, temperature should under all circumstances fall when the loss of heat is increased. This does not take place in acute rheumatism, puerperal, septic, and hectic fevers.

The theories which place the starting-point of the febrile phenomena in the nervous system alone—whether this be the central nervous system according to Virchow, or the sympathetic system of Claude Bernard, or the trophic nerves of Schiff—have neither been supported by clinical facts nor by experimental physiology. Mr. Teale's remarkable case, in which an injury about the upper part of the spine was followed by a temperature ranging for nine weeks from 109° to 122°, and even to 125°, with recovery, can not be taken as a proof that in all cases of fever the nervous system is at the root of the disturbance. And though I may omit the question of local myelitic inflammation as an agent in causing the febrile movement, this case, in my opinion, proves possibly just the opposite. In no other fever is there such a tolerance of an enormously high temperature, and, if in the great majority of cases even

much lower temperatures become fatal after a shorter time, this shows that there must be other factors in play.

No one of these factors, therefore, sufficiently explains by itself the pathogeny and semeiology of fever; it remains to be supposed that either two or all three of these factors are combined. The facts only justify us in the assumption that during fever heat-production is moderately and constantly increased, while there is an impaired action of the skin by which the loss of heat is diminished. The share of the nervous system has to be stated as being obscure till experimental physiology sheds a more satisfactory light on the relation between the phenomena of normal animal heat and the nervous system.

There are certain symptoms pretty constant in all fevers which require our attention. Of course, the chill is one of the most interesting of them, but, like so many other interesting phenomena in medicine, difficult of explanation. It consists of a diminution of the peripheral temperature, with a rise of the internal temperature, which occasionally attains its maximum at the termination of the chill, more frequently in the subsequent hot stage.

The fluctuations of temperature are, as is well known, of a different type in different fevers, and therefore can not be subject to general laws. The different types—as intermittent, remittent, continuous, and ephemeral, and the reasons for this nomenclature—are so well known that their enumeration may be sufficient. The division into febricula, pyrexia, and hyperpyrexia is useless, because of the difference in the subjective view of the observer.

The influence of fever on the pulse will not only vary with the degree of temperature and the time the organism is exposed to the influence of a high temperature, but also with the cause producing the fever. The pulse will nearly always be accelerated; in the beginning it is hard and full, and becomes smaller and softer in proportion to the intensity and the duration of the disease.

The blood is not altered so much during the fever as was formerly believed. The relative proportion of hæmoglobin and red blood-corpuscles to the mass of blood is only slightly diminished. In the lytic or epicritic period this diminution is considerable.

The carbonic acid given off by the lungs is increased in the proportion of eight to seven of the normal evolution. That the respirations are increased in fever is well known; in attempting to explain this fact we again meet the dilemma, Is this due only to the increased temperature, or also to nervous influence?

The urine is, during pyrexia, most frequently smaller in quantity, dark colored, and shows the following chemical changes:

The relative amount of phosphoric acid is diminished; we know that in certain conditions of chronic irritation the brain is relatively richer in mineral substances than normally; it is possible that the acutely irritated condition during fever depends on the same cause. Chlorate of potassium is present in moderate quantities, and chlorate of sodium in small amount. In opposition to former opinions, more recent researches have shown that urea is not increased to a great extent, while the uric acid and ammonia are present in greater quantities than normally. While this shows that the combustion of albuminous substances is increased, it also demonstrates that the process of disintegration is of such a nature as to prevent the formation of the normal terminal product. Albumin we only find in very intense fever, and the albuminuria may be due partly to altered conditions of the blood-pressure, partly to the parenchymatous degeneration of the kidneys, partly to an altered diffusion of albuminoids, and possibly to nervous influences.

Of other secretions, that of the salivary glands has been examined. It is diminished in quantity, sometimes absent altogether; its reaction is acid, although a free acid has not been determined as yet. In connection with the parotid gland, the suggestion of Mosler, to introduce a cannula into Stenson's duct for the removal of obstructions, is well worth mentioning, because in this way the post-febrile inflammation of the parotid may be prevented or its occurrence diminished.

There is a marked degree of dryness of the buccal and pharyngeal glands, and in almost all fevers we find a buccal and pharyngeal catarrh, by which the excessive thirst is better explained than by the so-called febrile desiccation. That there is a most intimate connection between the dryness of the buccal and pharyngeal mucous membranes and high temperature is shown by the moist state of the tongue after severe hæmorrhages and subsequent collapse in typhoid fever. The increase in thirst and consumption of water, with the diminution of the secretions, naturally lead to the question, What becomes of the water? It has been claimed that it becomes latent in the body during the fever, to be removed from it by the critical discharges. In support of this view, it has been said that the face of the patient during pyrexia looks turgid, while during the period of convalescence the countenance looks most emaciated; besides, that the blood of the fever patient was supposed to be richer in water than that of the normal system. The last point has not been demonstrated with sufficient exactness and conclusiveness to be taken as a proof. In order to settle the question satisfactorily, it will be necessary, in comparing healthy individuals with fever patients, to measure, besides the water in liquid form, the exact amount of liquid the normal individual takes in in the shape of solid food—as vegetables, etc.; furthermore, the increase in the amount of insensible perspiration and exhalation from lung and skin has to be calculated more accurately than has been done hitherto.

The anatomical changes which embrace the liver, kidney, spleen, pancreas, the heart muscle, blood-vessels, and the voluntary muscles, are only to be found after some duration of a high temperature. The parenchymatous degenerations of the liver and kidneys are easily explained by the high temperature and perverted innervation; in the kidneys the irritating character of the substances to be secreted may be of influence.

The heart muscle becomes very soft and pigmented, being filled with fat granules and brown pigment granules. The walls of the smaller blood-vessels often undergo fatty degeneration (thence tendency to capillary hæmorrhages); in the larger vessels the intima is swollen. In the voluntary

muscles we find two kinds of degeneration: the fatty and amyloid. It need hardly be mentioned that the latter does not allow of restitution. The spleen is enlarged; in the beginning it is hard and tense, while in the further course of fever it becomes softer and more friable; whether the general anæmia corresponding with the enlargement of the spleen is due to the circumstances that this organ deprives the other tissues of a great amount of blood, or whether it is due to a specific action of the spleen in the formation of blood-corpuscles, can not in the present state of physiology be decided.

The symptoms connected with the digestive tract are not always due to a gastro-enteritis, which, with some pathologists, plays such an important part. The anorexia, constipation, nausea, etc., can easily be explained by a lesser activity of the glands and by faulty innervation. Inflammation would not be so quickly removed as to allow appetite and digestive power to come back to their normal standard immediately after the cessation of the high temperature. I do not wish to assert that the influence of high temperature, unduly prolonged, may not be capable of producing inflammatory lesions of the stomach and intestines, but I do not believe in their constant presence in fever.

The functional derangements consist of a disturbance of general sensation and of psychical and motory functions. The ways in which these disturbances manifest themselves to the observer are so well known that they do not require special enumeration.

This completes the symptoms and phenomena which are more or less constant in all fevers; special lesions and their modifying influence on the course of the fever, as the intestinal lesion in typhoid fever or the skin lesion of variola, must be left to the consideration of special pathology.

COCAINE IN MINOR OPERATIONS.

By HENRY A. DU BOIS, Ph. B., M. D.,
SAN RAFAEL, CAL.

The following cases, in which this agent was used, may possess some slight interest:

A boy, aged twelve, had a flap of skin eight inches in length torn diagonally across the leg, just below the knee, by a kick from a horse. The wound was free from dirt, as the pantaloons were not torn. It was well washed with a 1-to-2,000 corrosive-sublimate solution, and a two-per-cent. cocaine solution in glycerin painted on the edges through which stitches were required. The cocaine solution was exhausted before the entire border of the wound had been coated. Twelve stitches were then taken, ten without any pain while conversing with the patient, but the last two caused great pain. The line of union was covered with subnitrate of bismuth, and a pad of absorbent cotton applied and retained by a bandage. Stitches removed on the fourth day. The wound united, except along the skin-border, which showed no union. Adhesive straps retained the flaps in position, and I saw the patient no more, but was told that the wound was fully united in less than a week.

A man, aged sixty-five, who had been partly paralyzed, asked for removal of small growth from the skin of the forearm. I had removed a similar growth several years before. The new growth was non-malignant, but started from the old one. I injected a four-per-cent. solution of cocaine under the bone by four punctures with a hypodermic syringe, and removed a piece of skin, one and a half by one inch, going down well upon the muscles. This was done during conversation, and without any sign of pain on the part of the patient. The wound was drawn together by sutures, as in the previous case, of silkworm-gut carbolized, and a bismuth and absorbent dressing applied, but the forearm was not put in a splint. The movements of the hand apparently tore out some of the stitches and more or less suppuration ensued, the wound gradually closing by granulation, but the time was upward of a month; at no time was there any pain.

I believe in both these cases the cocaine prevented union by first intention. In the first case I should have expected union of the greater portion of the skin-border in four days; in the latter, more or less adhesion between skin and subjacent tissue, although, doubtless, movements of the wrist interfered somewhat with perfect apposition—had I not used the cocaine, but simply contented myself with washing the wound with corrosive-sublimate solution and with dry bismuth dressing. In the latter case, too, the healing power was also probably deficient. In a small fistula of the anus the cocaine enabled me to lay it open and apply nitric acid without pain, and I noticed no postponement of healthy granulation.

In a case of chronic eczema of the face of fourteen years' standing, in which it became necessary to remove the beard on one side of the face, an injection of a four-per-cent. solution over the trifacial nerve, as it comes out in front of the ear, enabled me to remove every hair at two sittings and without pain. Applied to the inflamed base, or to the pustules after matter had been let out, I could detect no relief experienced from the interminable itching, which almost drove the patient wild; while a constant current of galvanism, passed from the front of the ear to the cheek and chin for ten minutes, would relieve the itching almost entirely for some eight hours.

In a case of severe neuralgia of the trifacial nerve involving the branches to the upper and lower jaw I injected one fifth of a grain of cocaine twice in front of the ear quite deep into the tissues. After each operation the woman became excited for five minutes or so, but there seemed no relief from pain, which was only afforded by opium and chloroform. In a severe case of rheumatic sciatica a hypodermic injection of one fifth of a grain afforded no relief, while the same quantity of morphine relieved pain, and a daily application of the constant current effected a permanent cure.

An application to the gum of a few drops of the two-per-cent. solution enabled a tooth to be extracted with hardly perceptible pain, while its introduction into a cavity where the nerve was supposed to be exposed seemed to afford no relief to pain. Cocaine seems to me to act through the mucous membrane and through the cellular tissue, but so far I have seen no action from a direct application to a nerve or to the skin. Even when the latter is excoriated, and when cocaine is injected into the cellular tissue or applied to the edges of a wound, it certainly seems to interfere with prompt union. I have so far made no experiments with this agent on blistered surfaces or burns. The cocaine used was procured from Dr. Squibb.

Book Notices.

The Use of the Microscope in Clinical and Pathological Examinations. By Dr. Carl Friedlaender, Privat-Docent in Pathological Anatomy at Berlin. Second Edition, Enlarged and Improved, with a Chromo-lithograph. Translated, with the permission of the Author, by Henry C. Coe, M. D., M. R. C. S., L. R. C. P. (London), Pathologist to the Woman's Hospital in the State of New York. New York: D. Appleton & Co., 1885. Pp. x–195. [Price, $1.50.]

This book is one of the most concise and comprehensive guides in *technique* which the student can obtain who undertakes microscopical examinations for clinical and pathological ends. It is divided into seven chapters, in which are described, in a plain, practical manner, the microscope and its accessories, reagents, micro-chemistry, methods of preparing specimens for examination, both of living and of dead tissues, the examination of fluids, the examination of tumors, etc.

Some beginners in microscopy are very apt to think that the work is essentially mechanical, and that if the mechanical process is perfect the desired pathological knowledge can be obtained readily; but this source of error is pointed out distinctly by the author. Another fundamental truth has also been mentioned, and that is that there are a number of minds which either never attain to a capacity for the more delicate histological examinations, or succeed only after long and painful training, and, it may be added, especially painful to the teacher. If these two ideas can become wide-spread, Dr. Coe, by his excellent translation, will have conferred a lasting benfit upon those who are interested in this department of scientific work.

The chromo-lithograph is an agreeable addition; but as one looks at the illustrations he may be led to wonder why pictures of the same objects are made to appear so different in different standard books.

A Guide to American Medical Students in Europe. By Henry Hun, M. D., Lecturer on Diseases of the Nervous System in the Albany Medical College. New York: William Wood & Co., 1883. Pp. vi–151.

This little book was received some months ago, and deserved an earlier notice. We commend it most heartily to the carefnl consideration of the class of readers for whom it is intended. We have no hesitation in saying that the author is a real benefactor to his younger medical brethren, in that he removes one of the most serious obstacles to the enjoyment and profit of a foreign trip. To know how, where, and what to study is half of the battle, and we congratulate Dr. Hun upon having so clearly and thoroughly discussed these questions. The author's introductory remarks are sensible and to the point. He discourages the student from going abroad to study until he has served his time in a hospital. Moreover, he deprecates too long a stay in foreign parts. "All of the time," he says, "that he (*i. e.*, the student) spends in Europe beyond two years is very apt to be to his disadvantage." This is an important and, as regards the average medical student, a true remark.

The statement regarding finances is judicious. We are glad to see that no attempt is made to impress the reader with the false notion that his expenses in Europe will fall far below his home expenditures. Men are frequently sadly disappointed at the unexpected demands upon their resources when they have been told that they could live abroad for "about one half" of what it costs in America.

We call particular attention to the advice as to learning German, for it is sound. The caution to students not to travel about too much from place to place, but to spend all of their time at two or three of the best medical centers, will commend itself to all who have had a practical acquaintance with foreign study. The general hints as to methods of study are worth a careful perusal.

In giving details about the different German cities, the author dwells with special care upon Vienna, Berlin, and Leipsic. Except in the matter of unimportant facts, such as vary from year to year, the information is clear and accurate. Medical study in France is not very strongly advised by the author, but he presents quite fairly the advantages which Paris offers.

In treating of the London medical schools, we can not help saying, a good deal of irrelevant matter might well have been omitted.

We are glad to read the short section upon the Dublin Rotunda Hospital, since there is a lingering feeling among some American teachers of obstetrics that the Rotunda is the *only* place in which to learn careful midwifery. We believe that this idea will be exploded, and meantime Dr. Hun is to be commended for coming boldly forward with the statement that "this hospital offers no advantages for study over those of Vienna, Prague, or Dresden, except that the English language is spoken in it."

On the whole, we believe that the "Guide" is an original book, the material is judiciously selected and arranged, and such errors as exist are not vital. It would be hardly fair to criticise too closely the literary style of a work which aims principally at clearness, rather than elegance, of expression; yet we trust that the author in his second edition (which we hope to see soon) will correct some of his awkward sentences, substitute the word "for" instead of "to" in the title, and add an index. With these slight emendations, and a condensation of the chapter on England, the little volume will challenge comparison with far more ambitious works.

System of Practical Medicine. By American Authors. Edited by William Pepper, M. D., LL. D., Provost and Professor of the Theory and Practice of Medicine and of Clinical Medicine in the University of Pennsylvania, assisted by Louis Starr, M. D., Clinical Professor of Diseases of Children in the Hospital of the University of Pennsylvania. Volume II. General Diseases (continued) and Diseases of the Digestive System. Philadelphia: Lea Brothers & Co., 1885. Pp. 3–19 to 1312, inclusive.

The general characteristics of this volume are analogous to those of its predecessor in the series, which it has followed with commendable punctuality. It even surpasses Volume I in size, and therein is open to criticism, for its bulk and weight are such as make it impossible to hold the book with comfort even in both hands. Another striking feature is the extent and minuteness of the index, rivaling in this respect the clinical index, so called, to Bartholow's "Materia Medica and Therapeutics," although it does not present the peculiar character which gives the special name to the latter. An index which bears to the text to which it refers the proportion of one page to ten (actually 117 to 1195) should be a remarkably good one to justify its presence in a volume already so large.

Passing to an enumeration of the individual articles, we find the opening one, on rheumatism, by Dr. R. Palmer Howard The second is by Dr. W. H. Draper, on gout, and is an example of clear and excellent English. While the discussion of the subject is full, he frankly confesses the limitations of our knowledge as to ætiology and the action of the most potent remedies. Dr. Jacobi, with an abundant citation of authorities, writes on rhachitis. Philip S. Wales, M. D., contributes two articles, the

one on scurvy, namely, and in the second part that on pseudo-membranous enteritis. In like manner Dr. I. Edmonson Atkinson writes on purpura, and on cancer and lardaceous degeneration of the intestines.

Diabetes is very satisfactorily discussed, in an article of moderate length, by Dr. Tyson, treatment, including the dietetic, hygienic, and medicinal, occupying much more space than pathology and pathogenesis. Dr. John S. Lynch writes on scrofula, and Dr. J. William White extensively on hereditary syphilis. This last author writes with the clearness of conviction so noticeable in the best American authorities on this subject, going fully and with plentiful references into the knotty question of the respective shares of father, mother, and fœtus in the transmission of the disease, including the curious theory of its latency in the maternal organism.

Under the subdivision of Diseases of the Digestive System we find a series of articles by Dr. J. Solis-Cohen on diseases of the mouth and tongue, of the tonsils, of the pharynx, and of the œsophagus, organs and regions in connection with which his name is a guarantee of thoroughness and familiarity. The functional and inflammatory diseases of the stomach are treated of by Dr. Samuel G. Armor, and his title is found to include gastralgia. Other gastric affections form the subjects of five articles by Dr. W. H. Welch, viz.: Simple Ulcer of the Stomach, Cancer of the Stomach, Hæmorrhage from the Stomach, Dilatation, and Minor Organic Affections. These articles are scholarly and enriched by copious references to literature and citations from it, while it is very gratifying to find in the matter of treatment especially so much attention given to the details and chemistry of alimentation, a remark which also applies to Dr. Tyson's article on diabetes.

Dr. W. W. Johnston writes on various affections of the intestines in six consecutive essays.

Dr. J. Lewis Smith contributes an article on the intestinal affections of children in hot weather. His views are well known, and it is particularly interesting to know his experience with the peptonized preparations which have formed such a feature of the recent management of children's diseases.

Of the remaining articles in the volume, those which will attract most attention are Dr. Hunter McGuire's on intestinal obstruction, Dr. Bartholow's treatise on diseases of the liver, and Dr. Alonzo Clark's on peritonitis. Dr. McGuire's article is much condensed, and he is forced to relegate much that is germane to his subject to surgical treatises, since it would be outside of the scope of this work.

All graduates of the College of Physicians and Surgeons will be glad to see the views of the venerable Prof. Clark thus authoritatively presented on a subject in which he felt so keen an interest. They will recognize the features which used to charm them in his lectures, the solid, slightly old-fashioned, personally characteristic style, with the quaint illustration drawn from his own experience.

Here is, then, a volume of interesting and valuable essays, which must still for the present stand chiefly upon their individual merits, for the work can not yet be looked upon as a finished whole, and its claims as a system fairly weighed. As it stands, it is very attractive, free from disfiguring pages of advertisements, and with illustrations which, if not numerous, are apposite.

Minor Surgical Gynæcology. A Treatise of Uterine Diagnosis and the Lesser Technicalities of Gynæcological Practice, including General Rules for Gynæcological Operations and the Operations for Lacerated Cervix and Perinæum and Prolapsus of Uterus and Vagina, for the Use of the Advanced Student and General Practitioner. By PAUL F. MUNDÉ, M. D., Professor of Gynæcology at the New York Polyclinic and at Dartmouth College, Gynæcologist to Mount Sinai Hospital, etc. Second Edition, Revised and Enlarged, with three hundred and twenty-one illustrations. New York: William Wood & Co., 1885. Pp. xxii–552.

(*Second Notice.*)

We hope to see the question of the "cicatricial plug" cleared up some day. If it is, it will be by the aid of the pathologist. It can not be allowed to rest entirely upon the dictum of the clinician. But it is in vain to argue upon a subject the pathology of which has been so much neglected. In the section upon the significance of cervical laceration the author summarizes his views as follows: "It thus appears that I consider only one half of all the lacerations of the cervix which occur as producing (symptoms?) and requiring treatment of any kind, and of these but one quarter, or one eighth of *all* lacerations, as absolutely requiring Emmet's operation. Surely I can not be reproached with being an advocate either of too universal pathological significance or of unconditional operative treatment of this lesion." The latter, it must be added, is rather an awkward sentence. The description of the operation leaves little to be desired. It gives the reader as clear a picture of the technique as could be drawn with the pen. Not a single practical hint or useful device is omitted. We see the operator at his work, describing each step as he goes along, beginning with an enumeration of the instruments and ending when the patient is removed to her bed. The possible dangers and complications of trachelorrhaphy are fully and squarely stated. Whatever faults Dr. Mundé's book may possess, want of frankness is not one of them. In this respect it is the true child of its author.

The subject of perinæorrhaphy receives the attention which its importance deserves. In his pathology the author leans perhaps more decidedly toward the "keystone" theory than some of his *confrères*. His recommendation of the primary operation will carry weight, and the description of its performance (page 487) is a very clever and graphic sketch, which furnishes a good example of the writer's rapid, nervous style. The details of the operation, both in partial and in complete lacerations, are exceedingly well given. It is in these practical directions that the author excels as a teacher and writer. Dissertations upon pathology are not his *forte*, but in describing gynæcological manipulations, as he has practiced them himself, he is perfectly at home. The operation proposed by Dr. Emmet, which, as Dr. Mundé remarks, is properly designed for the cure of proctocele, is duly described and figured. The author seems to have formed as clear an idea of the operation as any one has done, but we question most emphatically the statement that in passing the sutures they "are carried deep into the furrow and entirely under the raw surface, so as to pick up the separated fibers of the pelvic fascia." Even granting that the pelvic fascia has become detached (which is not by any means certain), how can the operator be sure that he is "picking it up" when he does not know where the torn fibers are? Dr. Mundé concludes that the new operation will "not supersede the old, except in comparatively slight external lacerations, where the redundancy and prolapse of the posterior wall predominates."

The various operations for the cure of cystocele, proctocele, and prolapsus are briefly described and figured. Reference is made to Emmet's "button-hole"; but it should be mentioned that urethrocele is only one of several conditions for the relief of which an artificial urethro-vaginal fistula is made by the proposer of the operation. We are glad to see that prominence has been given to Le Fort's operation for the cure of complete procidentia, for it deserves a more thorough trial in this country than it has had hitherto.

The latter part of Dr. Mundé's work bears evidences of hasty composition. After devoting ample space to trachelorrhaphy and perinæorrhaphy, he dismisses some of the other operations in a few words. The impression which the reader receives is that the author found that his book was assuming too great proportions, and resolved to condense it, even at the risk of giving it an appearance of unevenness and want of symmetry.

We have already referred to the chief excellence of the book—its practical character and the sound common sense which pervades it. The style is not always the most pleasing. While it is frequently clear and concise, it is sometimes rather involved. The author excels in descriptions; the purely didactic portions are occasionally marred by complicated sentences. The work is the product of years of experience and observation, and may be safely relied upon as being the outgrowth of the writer's own practice. He makes few statements which have not stood the test of his own judgment. Although there is much that might have been omitted without detriment either to the book or to its author's reputation as a careful writer, as it stands it will long continue a standard text-book.

Diseases of the Urinary and Male Sexual Organs. By William T. Belfield, M. D., author of "Relations of Micro-organisms to Disease"; Pathologist to the Cook County Hospital, etc. New York: William Wood & Co., 1884. Pp. vii–351.

The author states in his preface that the present work was prepared hastily and without sufficient time being allowed for revision. There are certainly but few signs of such haste, except in the last four chapters. The matter is well arranged, and prominence is given to several topics which have hitherto received but scanty notice in American treatises on urinary surgery. Following the German school, Dr. Belfield enters minutely into the anatomy of the subject, and devotes several chapters to the examination of the patient, one of which includes an admirable *résumé* of endoscopy. The physiology and pathology of the urine are as thoroughly discussed as is possible in a few pages. Chapters XVIII and XIX, on diseases of the kidney and bladder, are brief but satisfactory. We may add, with reference to that portion of the volume which is devoted to the diseases of the urinary organs, that it is excellent throughout, and the only regret in the reader's mind when he has finished it is that the book does not conclude here. The last forty pages, which treat of sexual disorders, are by no means so creditable to the author, since they bear evident marks of rapid composition and an apparent haste to finish as soon as possible.

Dr. Belfield has no reason to feel dissatisfied with his work. It is largely German in its tone, but it is in no sense either a compilation or an imitation. The author shows a personal knowledge of his subject, and many of his statements are founded upon the results of his own experiments.

It is hardly necessary to say that the reader will find in this book all of the latest ideas concerning urethral fever, as well as a clear and intelligible description of the methods of using Grünfeld's instruments, catheterizing the ureters, exploring the bladder through a perineal incision, etc. Nearly all of the woodcuts illustrate urinary sediments.

Medical German. A Manual designed to aid Physicians in their Intercourse with German Patients, and in reading Medical Works and Publications in the German Language. By Solomon Deutsch, A. M., Ph. D. New York: J. H. Vail & Co., 1884. Pp. v–336.

This will be found a most useful little book, especially for students who are contemplating a trip abroad. Written after the style of Ollendorf (though more dignified in its form), it contains just such dialogues as occur so often at the bedside and in the clinic. The first half of the volume contains a list of nearly six thousand words, such as are apt to occur in German medical works or lectures. The criticism to be made here is that the different parts of speech are bundled without regard to their relative importance or alphabetical arrangement. This fault is partly atoned for by the addition of a full English and German index at the back of the book.

The form of the dialogues is briefly this: A patient enters with bronchitis. "Where do you feel pain?" asks the physician. "I have soreness behind the breast-bone, and pain in my limbs," replies the patient, and so on.

When we remember how Americans of old were obliged to learn their medical German without special lexicons and other helps, such as the present manual, we can not be surprised at the fact that "studying abroad" was a far more formidable undertaking than it is now.

BOOKS AND PAMPHLETS RECEIVED.
